MUMPS MENINGITIS AND ORCHITIS WITHOUT PAROTITIS

R. S. DEWAR
M.D. Glasg., D.P.H.
PHYSICIAN-SUPERINTENDENT, COUNTY HOSPITAL, MOTHERWELL,
LANARKSHIRE

THE causal virus of mumps has a special predilection for the tissues of the gonads and the central nervous system, orchitis, meningitis, and meningo-encephalitis being well-known complications. The incidence of orchitis in men with mumps lies, according to [illegible] and Ronaldson (1940) between 17% and 33%. Mumps meningitis is generally accepted as a much less common complication, but the reported incidence varies widely.

Of 74 cases of mumps parotitis in males over the age of [illegible] Bang and Bang (1943) found that 49 (66%) had either latent or manifest meningitis. Holden et al. (1946) investigated 100 consecutive patients in hospital with proved mumps; 33 of these showed clinical signs of meningitis, and 33 had abnormal cerebrospinal fluid (C.S.F.). Frankland (194[illegible]) found that 30% of 234 cases of mumps among soldiers admitted to hospital had signs and symptoms of meningeal involvement. Steinberg (1944) showed this complication to be present in 10 of 165 patients with mumps. On the other hand, [illegible] (1932) states that the incidence is 0·15–0·5%. [illegible] Brooks (1918) in a military population in Service cases analysed 6815 cases of mumps and on a clinical basis reported none complicated by meningo-encephalitis.

This wide variation is partly due to the fact that some of the figures are based on clinical findings only, whereas other investigations have entailed routine examination of C.S.F., and any degree of pleocytosis is accepted as evidence of meningitis. Further, some groups under investigation have been patients admitted to hospital because of the severity of the attack, whereas other groups have included all the patients developing mumps.

The occurrence of orchitis and meningitis without parotitis has been noted in epidemics. Coe (1945) and Harris and Bethell (1938) have each reported one case, but the condition is comparatively rare, so a similar case is reported here.

CASE-RECORD

A man, aged 33, was admitted to the County Hospital, Motherwell, on May 10, 1949, as a case of meningitis. [illegible] days before admission he developed pain and swelling of the right testicle, which he attributed to a strain at work. He continued at his work as a motor-lorry driver for the next three days, but was then forced to stay in bed because of the pain in the testicle. Two days later he developed severe occipital headache and what he described as a shooting pain in the spine. There was some vomiting at this time, but his mental faculties were not impaired, and his vision was normal. The headache and neck pain persisted and were still present on admission. The patient was emphatic that he had at no time had pain or swelling in the region of the salivary glands, earache, or difficulty in mastication. However, fourteen days before the onset of his orchitis his son, aged 7 years, living in the same house, had developed typical mumps.

On examination the patient was a well-built intelligent man of good nutrition. He complained of headache and stiffness of the neck; he was somewhat listless but answered questions sensibly and with a normal reaction-time. His temperature was 100°F. There was well-marked nuchal rigidity without head-retraction. Kernig's sign was positive. Babinski's sign could not be elicited, tendon reflexes were normal, pup

·. **Williams** thanked Dr. Campbell for drawing his ıtion to the manifold cardiac causes of fainting. ər epilepsy or syncope can be primarily cardio- ılar or primarily cerebral. The point was to keep in our minds what was a fit and what was a faint manage them accordingly. In Adams-Stokes se the onset of unconsciousness is too rapid to be ıined by cerebral anoxia. The vascular framework e brain suddenly collapses and the semi-fluid brain psed too—a neurogenic cause.

LIVERPOOL MEDICAL INSTITUTION

The Intervertebral Disc

MEETING of the institution was held on Jan. 19, r the chairmanship of Prof. **Charles Wells**, the dent.

discussion on the intervertebral disc opened with a r on the disc's physical properties read, on behalf r. **W. J. Virgin**, by Mr. **G. V. Osborne**.

an investigation into their elastic properties, vertebral discs, were compressed with an Olsen əression-testing machine. The effect of intermittent constant loading, saturation with Ringer's solution, deliberate incision of the posterior part of the ılus was studied. It was found that the disc was to sustain very great loads without disintegrating. overy of the disc after deformation depended upon ibition of tissue-fluid by the disc and removal of deforming force: and the extent of recovery was lified by the duration of the force. Herniations disc material were produced infrequently despite ry loads during compression. Angled incisions into annulus produced definite interference with the ticity of the disc, but this did not happen with a ple linear incision. The elastic limit of the intertebral disc was relatively greater in mature adult cimens, and it would appear that the resistance to ıpression of an immature disc was related to the sence of the nucleus as a distinct entity.

Ir. **E. N. Wardle** spoke on conservative treatment of disc lesion. Such a lesion involved the whole bar spine: and spinal deformity was the one thing ch distinguished this disorder from the many other ses of similar pain. The usual history of intermittent kache, culminating in acute sciatic radiation, the ciation of muscle-spasm with the characteristic ıal list, and the strongly positive leg-raising test, confirmed this point. The so-called conservative ıtment was based on the accepted principle of correcı of a deformity and retention of the corrected position. the several methods, Mr. Wardle liked best the headpension plaster-and-celluloid jacket, which had ved successful in 70% of 269 cases. This method tabilised the spine; and under the temporary condins of artificial equilibrium a proportion of degenerated cs recovered their elasticity. The 30% of relapsing es were those in which there was no power to regain sticity; and this incapacity was probably the true lication for removal of the disc.

Mr. **A. Sutcliffe Kerr** held that operative treatment ruptured intervertebral disc should be considered ly when conservative treatment had failed. He lieved that three weeks' absolute bed rest was an equate form of conservative treatment; this rested ɜ intervertebral disc at least as well as when the tient was ambulant in plaster. Neurological signs re usually present, the most constant being limitation straight-leg raising and diminution of the ankle-jerk. ıdiology was not of much help, and myelography ould be employed only where the history was not aracteristic and there was suspicion of other ætiology, ch as cauda-equina tumour. The procedure of choice as a fenestration operation with minimal removal of bone, and in difficult cases hemilaminectomy gave an adequate exposure. Fusion of the spine simultaneously with the disc-removal was not recommended, but fusion might occasionally be necessary if there was subsequent severe back pain. Operative treatment of lumbago was not advisable. Mr. Kerr believed that lumbago was due to degenerative changes in the disc, but the pathology was not fully understood and the condition was better treated conservatively. Cervical-disc lesions were less common than lumbar-disc lesions; the operation was more formidable but became essential if there were signs of pressure on the cord. Lumbar-disc protrusions were sometimes so big that paraplegia resulted, and he had had twelve such cases. Statistics showed that 50–60% of cases of sciatica were cured by removal of the protruded disc, and a further 25–30% were substantially improved; 10–15% were not relieved; and only about 1% were made worse.

Mr. **F. C. Dwyer**, whilst agreeing with the general principle of treating patients suffering from sciatica conservatively in the first instance, felt that unless patients obtained quite early relief after the application of a plaster jacket, they should not be subjected to the continued discomfort of a jacket on the assumption that by this means the condition would clear up. If treatment by a plaster jacket was going to succeed, it would do so in 8–12 weeks. If there was not early relief from pain, if some symptoms still persisted after twelve weeks on conservative treatment, and if there was recurrence at a later date, operative treatment should be undertaken. The fenestration operation was a straightforward procedure and did not result in any residual weakness of the spinal column.

Insulin-induced Skeletal Abnormalities

Mr. **P. K. Duraiswami** said that in recent years it had been repeatedly shown that congenital malformations that were sometimes genetically determined could be produced in the offspring by maternal nutritional deficiencies, especially of vitamins; by the mother contracting rubella early in pregnancy; by irradiation; and by certain irritants, such as insulin, artificially introduced during development. With developing chick embryos the injection of insulin into eggs between the commencement and the seventh day of incubation had resulted in skeletal abnormalities such as spina bifida, partial or complete suppression of development of vertebræ, deformities of the feet ("club feet," divarication of claws), congenital dislocation of the hip, arthrogryphosis, and a developmental disturbance of bone resembling osteogenesis imperfecta.

The action of insulin seemed to be specific, since the injection into control eggs of physiological saline did not give rise to deformed chicks. Again, the injection of inactivated insulin caused no deformities, whereas if inactivated insulin was reactivated before injection, deformities resulted. Insulin seemed to affect primarily the part or organ which was in the most active stage of development or differentiation at the time of injection. It produced a definite hypoglycæmia, which persisted until about the twelfth day of incubation, after which the blood-sugar gradually returned to normal. In the chick the embryonic liver started storing glycogen about the twelfth day of incubation, and it was about this time that the carbohydrate metabolism was controlled to some degree by the secretion of insulin and the hormones of the suprarenal and pituitary glands. Since embryonic cells almost exclusively metabolised glucose during the early period of development, persistent insulin hypoglycæmia during this critical period might induce malformations by causing disturbances to cellular carbohydrate metabolism. These skeletal deformities had been prevented to a remarkable extent by injecting nicotinamide and riboflavin into the eggs along with insulin.

Why should some have them for so little cause? In epileptics the nervous centres were unstable, but little was known of the actual "trigger" mechanism which started the attack. In a faint a fall in blood-pressure explained the symptoms and the "trigger" was probably in the central nervous system—the onset following emotional disturbance suggested this, and again the fainting after standing for a long period. In postural hypotension there was already a great deal of evidence pointing to a central "trigger" mechanism, probably in the hypothalamus. The common characteristic for faints and fits, therefore, was an unstable nervous system. Hence it was not surprising that one should find both occurring in the same person, and that as time went on the influence of the centre responsible for fainting became less and that for epilepsy became greater. Finally he pointed out that there was no absolute means of distinguishing a fit and a faint unless the blood-pressure and pulse-rate could be watched during an attack. Although there might be a distinction between the two, they were related in their dependence on nervous instability.

Dr. DENIS WILLIAMS began by quoting Gowers's description of fainting and remarked that today we are discussing the matter in the same way as 50 years ago—we are a little further on, perhaps, but not much. He agreed that vasovagal attacks were rare, and that they should not be confused with "faints." He had seen two cases in the past year, both of which had been due to an infiltrating lesion in the region of the third ventricle. The electro-encephalograms (E.E.G.) of both patients with fainting and those who had epileptic fits showed bursts of fast waves in the frontal lobes. Therefore it appeared that the two conditions had a common factor, although he would not say from it that fainting was epilepsy. It was most unlikely that these waves related to the circumstance giving rise to the fit or faint, or directly to the reflex instability of the cardiovascular system, but it was likely that they reflected some instability in the hemispheres. Faints and fits must not be confused in their pathology or ætiology, but they seemed to be linked by the failure of the hemispheres to maintain consciousness in a special situation.

Dr. MAURICE CAMPBELL thought the distinction between fainting and epilepsy a very real one. He considered it unfortunate that the same term, "syncope," was used for the loss of consciousness in fainting and for the loss of consciousness in death, and suggested the term *tachyapsychia*, for use where there was sudden loss of consciousness in a faint, and *bradyapsychia*, where there was a more gradual loss of consciousness. While loss of consciousness in a sense concerned the physiologist and neurologist more than the cardiologist, Dr. Campbell thought they had a considerable knowledge of the many cardiac mechanisms which resulted in loss of consciousness. The common point in all the cases associated with cardiovascular lesions was cerebral anoxia. Too rapid functioning of the heart, as well as too slow, reduced the cerebral blood-flow. In general, bradyapsychia carried the graver prognosis. The patient was often not able to tell whether his failure was cardiac or cerebral. Dr. Campbell thought it was sometimes impossible to make a diagnosis of this on a single attack. How often are conditions like cerebral tumour present with loss of consciousness, and no other cardiovascular signs. The duration of unconsciousness was a real help in differentiating a cerebral and cardiac attack. A short loss of consciousness, lasting 2 minutes or up to 5 minutes, might be due to either; one lasting over 5 minutes was not likely to be cardiac, for if the heart stopped for 5 minutes the patient was dead. A difficulty was that some attacks started with cardiac arrest, but when the heart started again, consciousness did not return, because anoxæmia had been produced for long enough to cause cerebral damage showing itself in long unconsciousness. Stokes-Adams attacks where there was ventricular standstill in one side of the heart were often indistinguishable from fits and were also a good imitation of petit mal and grand mal. Standstill of the heart for 5–10 seconds would cause a sudden loss of consciousness. He recalled some American experiments in which a sphygmomanometer cuff was put round the necks of students and blown up to obstruct the cerebral circulation. Consciousness was lost in 5–10 seconds and recovered in the same length of time as soon as the cuff was allowed to collapse. All the students recovered completely in 2 minutes. The experiments were repeated on some schizophrenic patients who were kept unconscious for 110 seconds. These too were said to have recovered completely. Referring to Dr. Williams's observations with the electro-encephalograph, Dr. Campbell agreed that persons who were subject to fainting and those who had fits seemed to be a special type, but he did not think the two conditions were clinically related.

Dr. M. N. PAI, speaking as a psychiatrist, stressed the dangers of mistakenly diagnosing epilepsy as hysterical fits. Of 100 patients referred to him from military hospitals as cases of hysterical fits, only 31 had given a normal E.E.G.; 18 had definite evidence of epilepsy; 28 gave the spike-and-wave pattern associated with petit mal, and reports on the remaining 23 stated either that the E.E.G. suggested a predisposition to epilepsy or that it was compatible with epilepsy.

Dr. W. RITCHIE RUSSELL thought it was simpler to think of all people as being epileptics and regard the matter as one of threshold. He considered that anyone who suffered from automatic behaviour after an attack had had a fit, and he made a plea that someone who witnessed the attack should be sent with the patient to hospital. Forms should be posted to persons who had seen the attack. Patients who were liable to postural syncope should be told how they could stop an attack. There were various ways in which this could be done without drawing undue attention to oneself; the most effective was to bend down to tie up one's shoe lace; or—if stooping was out of the question—to contract the abdominal muscles vigorously.

Prof. E. P. SHARPEY-SCHAFER had found that one could faint anyone by bleeding him. If the person had a fall in blood-pressure which was great enough, he would inevitably have a fit. Professor Schafer did not think it was easy on the fit alone to distinguish between a fit and a faint. The pallor was of great interest. It had been shown that there was secretion of posterior pituitary hormone during the attack.

Dr. SHEILA SHERLOCK said that not only had secretion of the posterior pituitary hormone been observed, but also secretion of adrenaline. It seemed this might be the effect of faints and not the cause. She wondered whether the abnormal rhythm which Dr. Williams observed in the E.E.G. was the result of the faint or whether it might be causative.

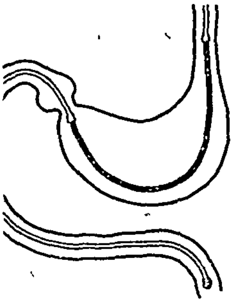
Dr. C. G. BAKER discussed unconsciousness occurring with coughing. Such cases, he recalled, were first described in 1876, when they were termed "laryngeal vertigo." All these cases occurred in men who were overweight, suffering from chronic bronchitis and emphysema. Dr. Baker thought the coughing led to cerebral anæmia, the high intrathoracic pressure preventing the return of blood to the right heart, and that the condition was commoner in men than women because men coughed with more force and severity. The prognosis was good.

Sir CHARLES SYMONDS, replying to the discussion, welcomed Dr. Williams's new concept that some people are more liable to lose consciousness than others, whether from epilepsy or not.

New Inventions

JEJUNAL TUBE FOR INTESTINAL LAVAGE IN URÆMIA

N the treatment of uræmia by intestinal lavage, nodified Miller-Abbott tube is very difficult to use ause the patients are restless and easily tired, and they n vomit, thus displacing the tube. Removal of the ge fluid by suction is often difficult and incomplete. these reasons Brun[1] and Selvaag[2] recommended junal tube for the inflow and a rectal tube for the out- of the lavage fluid. With this technique practically whole of the small intestine and colon are used for ysis. A gastric tube is impracticable for the inflow, use it will cause vomiting. Intubation with a jejunal tube in these very ill patients is also difficult. ctimes vomiting makes intubation impossible, and etimes the jejunal tube is regurgitated and coiled in the stomach. Frequent radioscopic control he position of the tube is often necessary, and is very fatiguing for the patient. A jejunal tube able for intestinal lavage must be capable of g easily and quickly introduced and must resist lacement by vomiting.



l tube made in three s. The stiff middle part, wn in black, prevents ing in the stomach and ors the terminal part ly in the small intestine.

At the Municipal Hospital at Kampen, in Holland, we have devised a tube which meets these requirements satisfactorily. It is constructed in three parts. The distal part (30–40 cm. long) is made of radio-opaque flexible rubber and has at its tip the usual metal olive. The middle part (about 30 cm. long) is made of stiff and rather hard 'Polythene' (outside diameter 3 mm., inside diameter 2 mm.). The proximal (nasal and œsophageal) part is made of polyvinylchloride ('Koroseal') tubing (outside diameter 5 mm.), which is very soft and less irritating to the nasal mucosa than are other erials.[3] The two ends of the middle part are inserted the tip of the proximal part and the beginning e terminal part and silk thread is tied firmly round joins.

efore intubation a mandrin, consisting of well- icated wire 0·5 mm. in diameter, is pushed through entire length of the tube. This mandrin has been n two curves—one to the right at the distal end, and to the front at the proximal end—but it is flexible ugh to allow the tube to be passed through the nose œsophagus. When the tip of the tube reaches the nach, the elasticity of the mandrin bends it to the right, preventing it from coiling in the fundus. Under oscopic control the tube is passed gradually along greater curvature to the pyloric region. The passage he tip of the tube past the pyloric sphincter needs leness and patience, for the operator must wait the periodic opening of the sphincter. As soon as tip reaches the duodenum, the mandrin must be ed out a few centimetres; otherwise the distal of the tube will be too stiff to pass through the ply curved duodenum. The tube is then easily hed further into the duodenum, and at the same time mandrin is pulled out more and more. When the middle part of the tube has reached the pylorus, mandrin is removed altogether. The middle part not be passed beyond the pylorus, but the distal t is now firmly anchored in the duodenum and cannot displaced by vomiting.

Vith this technique the small intestine has been ubated in a few minutes. Fluoroscopy for so short a e is not a serious disadvantage. We have used this e successfully on uræmic patients when intubation with the usual type of duodenal tube had proved impracticable because of severe vomiting.

Sometimes, during irrigation, the lavage fluid is partly regurgitated into the stomach and causes vomiting. We therefore now fasten a rubber balloon just proximal to the tip of the tube, and fill it with air, after it has passed the pyloric sphincter, through a thin flexible polythene tube (diameter 2 mm.) fastened alongside the main tube. This balloon effectively prevents lavage fluid being regurgitated into the stomach.

Reviews of Books

History of the Primates: an Introduction to the Study of Fossil Man

W. E. LE GROS CLARK, F.R.S., professor of anatomy in the University of Oxford. London: British Museum. 1949. Pp. 117. 2*s.* 6*d.*

MAMMALS, which evolved about 150,000,000 years ago in the Mesozoic age, gave rise to small tree-shrews which flourished at the beginning of the Tertiary age about 70,000,000 years ago. From these in turn evolved lemurs, tarsiers, apes, monkeys, and man. All of them, from tree-shrews to man, are classed zoologically as Primates, the subject of this beautifully clear, admirably concise, and plentifully illustrated account. Intelligible reasons are given why apes, monkeys, and man are grouped together as Anthropoids, apes and man as Hominoids, and the different forms of modern and fossil man as Hominids. The puzzle to be solved is the line of evolution of man from the tree-shrews. Prof. Le Gros Clark shows that monkeys are not on that line, but that both monkeys and apes are in all probability derived from tarsiers. The apes gave rise both to other apes, not on the line, and to man; and it remains to be found from which apes man is descended. Candidates for the position of ape ancestor of man are rapidly being dug up in South Africa. Prof. Raymond Dart's discovery of Australopithecus in 1925 is ancient history now, but Dr. Robert Broom is still finding others. Unfortunately their geological dates are doubtful because they come from unstratified deposits; but the associated fauna points to either the end of the Pliocene age or the beginning of the Pleistocene age, which began about 1,000,000 years ago. The anatomy of these South African apes shows many affinities with the Hominids, but the earliest Hominids, *Pithecanthropus erectus* from Java and *P. pekinensis* from China, are also assigned by some geologists to the early part of the Pleistocene age, and artefacts first appear at the beginning of the same age, if not earlier. Moreover, a Hominid remarkably like, if not identical with, *Homo sapiens* was found at Swanscombe, Kent, in an Acheulian context of some 250,000 years ago, and a lower jaw with a well-developed chin was found in association with pebble tools and a fauna of very early Pleistocene type in East Africa.

Having pointed out that the special feature in the evolution of the Primates is the growth and elaboration of the brain, Prof. Le Gros Clark says: "If Man has gained his intellectual dominance over his fellow creatures by concentrating his evolutionary energies on the development of his brain, it remains to be seen whether he can now maintain his position by contriving a method of living in orderly relations with members of his own species"—or become extinct.

Woman and Happy Marriage

ALLAN WORSLEY, M.B. Birm. Birmingham: Cornish Brothers. 1949. Pp. 318. 21*s.*

NO-ONE can doubt the sincerity of the author of this book, though his self-assurance may occasionally raise a smile. Much of it reads like the after-supper musings, reminiscences, and good advice of an elder brother G.P., and from the liberal mixture of exhortation and explanation a number of young people may find some help in their marital difficulties. The value of the book lies in its insistence on feelings as the basis of so many difficulties and in the author's admiration and appreciation of women. There is a risk, however, that those people who

MANCHESTER AND LIVERPOOL PÆDIATRIC CLUBS

Prematurity

THE first annual joint meeting of these two clubs was held in Liverpool on Jan. 6, with Miss ISABELLA FORSHALL (Liverpool) in the chair.

A discussion on prematurity was opened by Prof. W. I. C. MORRIS (Manchester), who spoke on the causes and prevention of prematurity. The commonest recognisable causes were toxæmia of pregnancy, antepartum hæmorrhage, plural pregnancy, and hydramnios; but in some 40% of cases no definite cause could be elicited. Malnutrition might be an associated, if not the primary, ætiological factor. The prophylaxis of prematurity was a matter for sociological study and communal action. The provision of many more antenatal beds was necessary to enable the obstetrician to institute treatment of toxæmia of pregnancy at its very commencement, and to allow of inpatient study of those conditions which appeared to predispose to prematurity. Not all the beds need be in hospitals; antenatal rest-homes would be particularly valuable.

Dr. J. D. HAY (Liverpool) discussed high-protein feeding for the premature infant. He described his experience at Mill Road Hospital where three groups, each of 15 premature infants, had been studied. Each group received the same routine care, and all infants were fed with expressed breast-milk (E.B.M.) until breast-feeding was established. 'Hepovite' was added to E.B.M. (gr. 18 to the oz.) in group 1 so as to give an additional 2·2% amino-acid content. Group 2 received an additional 4·4% 'Dextri-maltose,' and group 3 E.B.M. alone. Observations of the weight-gains, the total plasma-protein levels, and the hæmoglobin levels showed that the addition of hepovite had no influence on the rate of weight-gain; that the plasma-protein levels rose somewhat during the first few weeks when maximum doses of hepovite were given, but that these levels were not maintained; and that the hæmoglobin levels in the three groups were similar.

Dr. SYLVIA GUTHRIE (Manchester) reviewed the cases of 280 premature babies admitted in the first two weeks of life to the Duchess of York Babies' Hospital between January, 1944, and September, 1949, and attempted to assess the infection-rate and the mortality due to infections. Within this group the mortality-rate fell in 1947 and 1948 but rose slightly in 1949, when there was an increase in the number of deaths within forty-eight hours of admission. Despite this increase, there was a pronounced drop in the percentage of deaths due to infection. This fall coincided with the transfer of infants from the old premature-baby wards to a new cubicled unit; and Dr. Guthrie concluded that the decrease was due to this isolation in cubicles with a fully trained nursing-staff throughout the twenty-four hours, and to improved ward-cleaning facilities.

Dr. A. E. MCCANDLESS (Liverpool) spoke of the value of straight X-ray films of the abdomen in the diagnosis of intestinal obstruction in the newborn. Gas was present in the stomach immediately after birth, and within the first hour the proximal portion of the small bowel was outlined. At the third hour the colon could be visualised, and by the eighth hour gas in the pelvis. In Liverpool an investigation was being undertaken to determine the rate of passage of gas through the bowel of premature infants; preliminary observations suggested that this was similar to that in full-term infants. In congenital intestinal obstruction, arrest of the passage of gas could be seen on the straight X-ray film a few hours after birth. A barium meal, which involved the risk of aspiration, was a less safe procedure.

Dr. P. D. MOSS (Liverpool) described an apparent periosteal reaction found in radiographs of the long bones of premature infants. Of 63 such infants 26 had shown these changes in one or more bones. Syphilis was excluded; and the explanation was still unknown.

MANCHESTER MEDICAL SOCIETY

Peritoneal and Retroperitoneal Effusions

AT a meeting on Dec. 7 Prof. G. A. G. MITCHELL gave a lecture on the Spread of Effusions in the Peritoneal and Retroperitoneal Regions. From clinical and experimental evidence, he argued that the orthodox [illegible] about the spread of fluids from the right subhepatic space (Morison's pouch) were wrong. The experiments involved the production of artificial visceral perforations, the injection of barium emulsion under controlled pressure, and subsequent study on the radiographic screen. They revealed that an effusion in the right subhepatic space escaped into the right infracolic space through the interval between the quadrate lobe of the liver, the gall-bladder, the transverse colon, and the falciform ligament, and not, as was usually stated, by passing through the interval between the liver, right kidney, and hepatic flexure. Overspill was facilitated by the relative narrowness of the transverse mesocolon to the right of the midline. The right subphrenic space escaped involvement in the early stages, possibly because fluid accumulating in the pouch pressed the thin inferior margin of the liver against the parietes, so producing a valvular seal.

The fluid passed downwards and outwards in the right infracolic space to the ileocæcal region; some of it flowed into the right external paracolic groove and then spread upwards to invade the right subphrenic space. It also extended into the left infracolic space, passing over or between the coils of ileum or [illegible] the cæcal margin, and then it gradually infiltrated upwards to involve the left subphrenic space, and downwards to invade the pelvis, which often escaped contamination when the body was recumbent unless large amounts of fluid were injected. Contrasting diagrams showed how the methods of spread differed from those described in monographs and textbooks.

The spread of fluids in the retroperitoneal regions was also influenced by anatomical arrangements, and investigations and experiments had been devised in order to reveal how these factors determined the spread of fluid from the perinephric space. The descriptions of the renal fascia given in textbooks of anatomy and applied anatomy were all more or less inaccurate; the layers of fascia were united along the entire renal and suprarenal margins and not only above and laterally as was usually stated. There was a weak spot in the vicinity of the ureter, and extension from the perinephric space into the retroperitoneal region invariably commenced in this area. Medially there was neither actual nor potential communication between the opposite perinephric spaces because the renal fascia blended with the mass of connective tissue surrounding the great vessels and in the root of the mesentery.

An effusion in the perinephric space or retroperitoneal region remained unilateral unless the pressure exceeded 100 mm. Hg, and then extension to the opposite side might take place in the lumbosacral, renal hilar, and suprarenal regions, in that order of frequency. If a rupture occurred in the hilar region, the anterior layer of renal fascia and adjacent peritoneum usually gave way with involvement of the peritoneal cavity, but the opposite perinephric space was not invaded. The [illegible] of extension into the pelvis with invasion of the pararectal and paravesical areas was also demonstrated, and [illegible] the occasional spread into the inguinal canal and scrotum in the loose extraperitoneal tissues around the processus vaginalis peritonei.

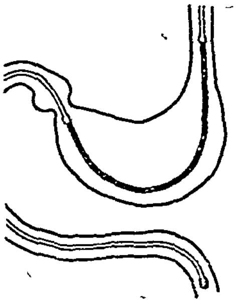
'EJUNAL TUBE FOR INTESTINAL LAVAGE IN URÆMIA

ɿ the treatment of uræmia by intestinal lavage, ıodified Miller-Abbott tube is very difficult to use .use the patients are restless and easily tired, and they ɑ vomit, thus displacing the tube. Removal of the ge fluid by suction is often difficult and incomplete. these reasons Brun [1] and Selvaag [2] recommended unal tube *for the inflow and a rectal tube for the out-* of the lavage fluid. With this technique practically whole of the small intestine and colon are used for ƴsis. A gastric tube is impracticable for the inflow, use it will cause vomiting. Intubation with a jejunal tube in these very ill patients is also difficult. etimes vomiting makes intubation impossible, and ɜtimes the jejunal tube is regurgitated and coiled in the *stomach. Frequent radioscopic control* he position of the tube is often necessary, and is very fatiguing for the patient. A jejunal tube *ıble for intestinal lavage must be capable of* g easily and quickly introduced and must resist lacement by vomiting.



al tube made in three ts. The stiff middle part, ıwn in black, prevents ling in the stomach and hors the *terminal* part nly in the small intestine.

At the Municipal Hospital at Kampen, in Holland, we have devised a tube which meets these requirements satisfactorily. It is constructed in three parts. The distal part (30–40 cm. long) is made of radio-opaque flexible rubber and has at its tip the usual metal olive. The middle part (about 30 cm. long) *is made of stiff and rather* hard 'Polythene' (outside diameter 3 mm., inside diameter 2 mm.). The proximal (nasal and œsophageal) part is made of polyvinylchloride ('Koroseal') tubing (outside diameter 5 mm.), which is very soft and less irritating to the nasal mucosa than are other erials.[3] The two ends of the middle part are inserted the tip of the proximal part and the beginning ɑe *terminal* part and silk thread is tied firmly round joins.

efore intubation a mandrin, consisting of well- icated wire 0·5 mm. in diameter, is pushed through entire length of the tube. This mandrin has been ·n two curves—one to the right at the distal end, and to the front *at the proximal end—but it is flexible* ugh to allow the tube to be passed through the nose œsophagus. When the tip of the tube reaches the nach, the elasticity of the mandrin bends it to the right, 's preventing it from coiling in the fundus. Under ioscopic control the tube is passed gradually along greater curvature to the pyloric region. The passage the tip of the tube past the pyloric sphincter *needs* tleness and patience, for the operator must wait the periodic opening of the sphincter. As soon as tip reaches the duodenum, the mandrin must be led out a few *centimetres; otherwise the distal* 't of the tube will be too stiff to pass through the ırply curved duodenum. The tube is then easily ,hed further into the duodenum, *and at the same time* mandrin is pulled out more and more. When the f middle part of the tube has reached the pylorus, mandrin is removed altogether. The *middle* part ınot be passed beyond the pylorus, but the distal 't is now firmly anchored in the duodenum and cannot displaced by vomiting.

Vith this technique the small intestine has been ubated in a few minutes. *Fluoroscopy for so short a* ıe is not a serious disadvantage. *We have used this* ɔe successfully on uræmic patients when intubation with the usual type of duodenal tube had proved impracticable because of severe vomiting.

Sometimes, during irrigation, the lavage fluid is partly regurgitated into the stomach and causes vomiting. We therefore now fasten a rubber balloon just proximal to the tip of the tube, and fill it with air, *after it has passed the pyloric sphincter, through a* thin flexible polythene tube (diameter 2 mm.) fastened alongside the main tube. This balloon effectively prevents lavage fluid being regurgitated into the stomach.

Reviews of Books

History of the Primates: an Introduction to the Study of Fossil Man

W. E. Le Gros Clark, F.R.S., professor of anatomy in the University of Oxford. London: British Museum. 1949. Pp. 117. 2*s.* 6*d.*

MAMMALS, which evolved about 150,000,000 years ago in the Mesozoic age, gave rise to small tree-shrews which flourished at the beginning of the Tertiary age about 70,000,000 years ago. From these in turn evolved lemurs, tarsiers, apes, monkeys, and man. All of them, from tree-shrews to man, are classed zoologically as Primates, the subject of this beautifully clear, admirably concise, and plentifully illustrated account. Intelligible reasons are given why apes, monkeys, and man are grouped together as Anthropoids, apes and man as Hominoids, and the different forms of modern and fossil man as Hominids. The puzzle to be solved is the line of evolution of man from the tree-shrews. Prof. Le Gros Clark shows that monkeys are not on that line, but that both monkeys and apes are in all probability derived from tarsiers. The apes gave rise both to other apes, not on the line, and to man; and it remains to be found from which apes man is descended. Candidates for the position of ape ancestor of man are rapidly being dug up in South Africa. Prof. Raymond Dart's discovery of Australopithecus in 1925 is ancient history now, but Dr. Robert Broom is still finding others. Unfortunately their geological dates are doubtful because they come from unstratified deposits; but the associated fauna points to either the end of the Pliocene age or the beginning of the Pleistocene age, which began about 1,000,000 years ago. The anatomy of these South African apes shows many affinities with the Hominids, but the earliest Hominids, *Pithecanthropus erectus* from Java and *P. pekinensis* from China, are also assigned by some geologists to the early part of the Pleistocene age, and artefacts first appear at the beginning of the same age, if not earlier. Moreover, a Hominid remarkably like, if not identical with, *Homo sapiens* was found at Swanscombe, Kent, in an Acheulian context of somé 250,000 years ago, and a lower jaw with a well-developed chin was found in association with pebble tools and a fauna of very early Pleistocene type in East Africa.

Having pointed out that the special feature in the evolution of the Primates is the growth and elaboration of the brain, Prof. Le Gros Clark says: "If Man has gained his intellectual dominance over his fellow creatures by concentrating his evolutionary energies on the development of his brain, *it remains to be seen whether* he can now maintain his position by contriving a method of living in orderly relations with members of his own species"—or become extinct.

Woman and Happy Marriage

Allan Worsley, M.B. Birm. Birmingham: Cornish Brothers. 1949. Pp. 318. 21*s.*

NO-ONE can doubt the sincerity of the author of this book, though his self-assurance may occasionally raise a smile. Much of it reads like the after-supper musings, reminiscences, and good advice of an elder brother G.P., and from the liberal mixture of exhortation and explanation a number of young people may find some help in their marital difficulties. The value of the book lies in its insistence on feelings as the basis of so many difficulties and in the author's admiration and appreciation of women. There is a risk, however, that those people who do not respond to his hearty advice may feel that there is no hope for them: he seems to consign them to a limbo of non-coöperators who may or may not get help from psychiatrists. His views on the upbringing of children seem excessively repressive. Also his facts are sometimes questionable: a Dutch cap does *not* fit by suction.

Vitaminology

The Chemistry and Function of the Vitamins. WALTER H. EDDY, PH.D., emeritus professor of physiological chemistry, Teachers College, Columbia University, New York. Baltimore: Williams & Wilkins. London: Baillière, Tindall, and Cox. 1949. Pp. 365. 46*s.* 6*d.*

VITAMINOLOGY is not a pleasant word, and many people will disagree with the statement on the dust-cover that "for the first time in a single volume, this monograph covers the vitamin field in an up to date manner"; but that is not to say that this is not a good book. Professor Eddy has been associated with vitamin research and teaching for a great number of years, and his experience and knowledge have enabled him to produce a book on the vitamins which many will read with pleasure and profit. The historical touches are particularly pleasing, and the simplicity of the presentation makes the book easy to read. The vitamins are considered in turn, and each is discussed under the headings of action, chemistry, practical importance, and requirements. Their chemistry and chemical relations are set out in a way that should prove very valuable to those who wish to understand this part of the subject—and who does not, now that the mode of action of these mysterious minutiæ is beginning to become clear? Each section or chapter closes with a substantial body of references; so additional information on any point should be easy to obtain. B_{12} does not appear on the table of contents but is dealt with, satisfactorily and in an interesting fashion, under "other postulated vitamins."

No book is perfect, and no human being could compress all the present knowledge about vitamins into a book of this size; but the claim on the dust-cover is too challenging to escape some comment. The author has inevitably relied on previous vitamin reviews for much of his information, and some of this is a little out of date; there is no mention of the interesting effects of polar-bear liver in the section on vitamin-A overdosage, and no reference to any of the Medical Research Council's experiments at Sheffield on vitamin A or C requirements. Hyperkeratosis is not given as a sign of C-deficiency, and the Danish work on phytase has been overlooked. Yet in spite of such reservations, Professor Eddy's book (and its preface by Casimir Funk) may be commended to the teachers and students for whom it was written and also to many others who want clear information on a quickly growing and important subject.

Advances in Pediatrics

Vol. IV. Editors: S. Z. LEVINE; ALLAN M. BUTLER; L. EMMETT HOLT, jun.; A. ASHLEY WEECH. London and New York: Interscience Publishers. 1949. Pp. 316. 52*s.*

VOL. IV of *Advances in Pediatrics* differs from vols. I–III in having half its articles contributed by European authors. It would be satisfying to say that this international flavour has improved its value; but in fact the contributions of most worth and containing most new material derive from the United States. The authors of the seven articles tend perhaps to give too detailed an exposition of their personal experience, and the editors have selected some subjects on which there is nothing strikingly new to report and which have not yet been developed beyond the stage of uncoördinated facts.

Examples are erythema nodosum and the reticulo-endothelioses. The criticism also applies to E. Freudenberg's article on cystinosis, the classification of which is in a very muddled state. It might have simplified the author's task if he had considered the part played by renal tubular incompetence in causing amino-aciduria; for C. E. Dent has shown that the blood level of amino-acids may be normal in such cases of resistant rickets with dwarfism, even if there is heavy amino-aciduria as well as the more common glycosuria, proteinuria, and excessive phosphaturia. There is thus no need in these cases to postulate any inborn error of metabolism of amino-acids except possibly in the renal tubule cells.

A. Lichtenstein presents with force and skill his plea for a free diet in diabetes. When, however, one reads his destructive criticism of the dietary disciplinarians and assesses what in fact he recommends for his own patients, one is left with the impression that even his diet has significant controls, as indeed it must to avoid hypoglycæmia and insulin fatalities. The real test of Lichtenstein's treatment is, of course, its results; and, though his early ones are promising, the later ones will throw more light on the possible harm done by hyperglycæmia per se.

Two American articles, one on the treatment of congenital syphilis with penicillin and the other on combined immunisation, are comprehensive reviews of a mass of literature. Hence they make intricate reading, and it is a relief to follow a story of more individual achievement in Ingraham's and Matson's clear and well-illustrated article on subdural hæmatoma in infancy.

There are more misprints than one would expect in a volume otherwise so well produced; but except perhaps for that on p. 274, where cystine appears instead of cysteine, they are unlikely to cause confusion. Besides a detailed index relating to this volume there is a cumulative author and subject index including also the [illegible] the three earlier volumes. This collection of articles provides information of wide interest and not easily obtainable elsewhere.

Textbook of Histology (5th ed. London: Heinemann Medical Books. 1949. Pp. 432. 25*s.*).—Miss Evelyn E. Hewer, D.SC., has revised her good and well-known textbook. Besides giving the basic minute structure of organs and tissues she has described the reactions of tissues so that students may learn to distinguish between physiological variations of structure, and those which fall into the realm of pathology. The illustrations in this book were always good, and have now been augmented with new photographs. With the help of Dr. L. M. Dickinson, Dr. Hewer has brought the terminology into line with that used currently by anatomists—a language so fleeting that he who runs may read.

Health is Our Adventure (London: Church Missionary Society. 1949. Pp. 95. 3*s.*).—This little book, by Dr. G. Jeffree, is written with charm and humour as well as with deep missionary zeal. Within its small compass it shows how modern medicine, particularly its preventive aspects, can be aligned with missionary pioneering; and the adventure is there no less than it was in earlier days. The writer knows village life in South India well; and the book touches also on conditions of medical work in other parts of Asia and Africa. The many illustrations show vividly how modern medical practice can be adapted to conditions in hospitals and health centres in backward areas. The book should appeal strongly to the pioneer spirit in medical students and nurses in training.

The Premature Infant: Medical and Nursing Care (2nd ed. Philadelphia and London: J. B. Lippincott. 1949. Pp. 381. 42s.).—For many years Prof. Julius H. Hess and Miss Evelyn Lundeen, of Chicago, have made a special study of the premature baby, and this book is based on their experience. The new edition has been thoroughly revised and modernised. Additions have been made to the sections on follow-up care and on physical and mental development, and whole chapters are now devoted to medical therapeutics, erythroblastosis fœtalis, the eyes, the ears, and men[illegible]. These chapters include the use of sulphonamides and antibiotics in the premature infant, an up-to-date account of hæmolytic disease including the present knowledge of haptens, and a section on retrolental fibroplasia, a condition causing blindness in premature babies. The sections on procedure for manual expression of breast-milk and immunisation, have been improved, and the chapter on incubators now includes descriptions of the Gordon Armstrong X4 baby incubator and the Chapple isolotte, both of which are in limited use in this country. The last two chapters give valuable suggestions for the teaching of the care of the premature baby, and a comprehensive picture of the organisation of this care in the various cities and States of the U.S.A. A useful section on the care of the full-term infant appears as an appendix. Most of the original illustrations are still present and many new ones have been added. The book is full of interest for nurses as well as doctors, since nursing procedures are given in detail.

THE LANCET

LONDON: SATURDAY, FEB. 11, 1950

Atomic Defence

ROM the studies made at Hiroshima and Nagasaki
have a fair idea of the medical problems likely to
e after an atomic explosion in a populous area.
RK[1] points out that the explosion may cause
ries in three ways: (1) by its actual force, which
y hurt people up to $3^{1}/_{2}$ miles away; (2) by heat,
h a range of $2^{1}/_{2}$ miles; and (3) by radiation, with
ange of 2–3 miles. The direct injuries may be
sed either by blast, or by flying fragments of
terial or falling debris; blast injuries are relatively
, but 70% of casualties are likely to be injured by
gments or debris. Burns are also of two types:
re are *flash burns*, which may affect people in the
n as far as $2^{1}/_{2}$ miles away, and then there are
ondary burns from fires caused by the explosion.
rious estimates put the proportion of casualties
o have burns—usually in addition to injuries—at
m 65% to 90%. About 35% of casualties have
iation injuries. These are mostly due to direct
osure to γ-rays, but they may also be caused by
osure to substances rendered radioactive by the
losion; and there is a further unknown proportion
o have inhaled radioactive dust or who have
ested substances contaminated by such dust or
ve even been rendered radioactive themselves. This
eading of radioactive dust and possibly water-
oplets by the explosion and by subsequent wind is
e of the main and most incalculable dangers that
y system of atomic defence would have to face.
cause it is so insidious; and obviously it may
d to contamination of water, food, clothing, and
edical supplies.

To avoid contamination, the rescue services would
ve to be at least 3 miles from the explosion, and
the leeward side perhaps even further away.
l rescue workers would have to be provided with
otective clothing and a complete change, including
derclothing. Their duty would be simply rescue
d first-aid in the contaminated area—stopping
emorrhage, immobilising broken limbs, and so on
and they would concentrate on getting the casualty
the decontamination centre and the "base"
ospital as soon as possible. Forward blood and plasma
ansfusion, so well exploited in the late war, is no
se in atomic work; nor must hypodermic injections
e given: morphine, if given at all, must be given
y mouth. PARK holds that rescue-workers should
oncentrate on casualties beyond a 2-mile radius from the explosion centre, since those within this radius are likely to die anyhow of radiation sickness, unless shielded by, say, buildings. Extensive provision will have to be made for decontaminating casualties; and the necessary buildings, with good water-supply and ventilation, and the protective arrangements for workers, cannot easily be improvised. After decontamination, the casualty can go to hospital. Here his wounds, and almost certainly his burns, will be treated on established lines. The many cases of burns will call for good laboratory facilities and ample blood and plasma for infusion. In addition, radiation sickness will have to be watched for, and here the important criterion is the white blood-cell count. PARK thinks that if the count is less than 2000 per c.mm. treatment is a waste of time and material; if the count is over 2000 per c.mm. a transfusion of 500 ml. of whole blood is given, and if it remains above this figure twenty-four hours later the full supportive treatment for radiation sickness can be undertaken with a good chance of success. One of the peculiarities of atomic warfare is that, when the immediate casualties have been dealt with, the defence planners must prepare for a fresh wave of radiation-sickness cases 8–14 days after the explosion. Those affected may have had some sickness on the first day. Thereafter they are quite well until symptoms associated with granulopenia appear; then follow hæmorrhages due to thrombocytopenia and increased heparin in the blood; and after about three weeks—if the patient survives—comes an aplastic type of anæmia. This syndrome requires intensive treatment by repeated blood-transfusion, penicillin against infection, and intravenous *toluidine-blue to control the hyper*heparinæmia. In each case a large amount of laboratory work is clearly needed for proper control. The later effects of radiation on the blood have so far not been conspicuous. SNELL, NEEL, and ISHIBASHI[2] carefully examined the blood of some 900 people in Hiroshima who had had epilation of the scalp after exposure to the atom-bomb explosion two years before. Compared with the population of a nearby town, their red-cell count was 1·6% lower and their hæmoglobin 2·1% lower: the white-cell counts were not significantly different.

Here, then, in brief outline, are the problems. On what scale must the defence services be provided? Some guiding figures are known. The Hiroshima bomb devastated 4 square miles, killed about 60,000 people, and injured some 69,000; the Nagasaki bomb blew up $1^{1}/_{2}$ square miles, killed 39,000, and injured 25,000. PEARSE and PAYNE[3] estimate that at Hiroshima there were probably 34,000 severely burned casualties, and calculate that to cope with this number of burns 170,000 "professional persons" (doctors, nurses, technicians) would be needed, eight thousand tons of medical supplies (enough to fill a Liberty ship) would be used, and the cost would be about 10 million dollars. And all this is for only one aspect of treatment. PERRIN LONG[4] believes that the explosion of a single bomb of the Hiroshima type would create within the first twenty-four hours the need for 300 first-aid teams, 500 stretcher-bearer teams, 400 casualty-collection points, and 24 neuropsychiatric centres. No wonder **Park** says that it is probably impossible to handle all the cases; we can only try to save some. And these grim estimates apply only to the original atomic-bomb explosions. Bombs capable of causing ten times this destruction are reputed to be a practical possibility, if not already made; and the proposed hydrogen bomb is said to be many times more powerful and destructive than even these.

[4] Quoted by Snyder, L. T. *Med. Ann. Distr. Columbia*, 1949, 18, 505.

Will any defence system be able to do more than rescue those at the fringe of the affected area? And if both sides in a war use these engines of obliteration, who will call himself the victor? It is of course suggested that fear of retaliation may prevent resort to atomic bombs and biological warfare.[5] But those who start wars are prepared to take risks; and it is as well that everyone should realise what is involved in the "atomic defence" of which some politicians speak so glibly.

Thiosemicarbazone in Tuberculosis

Here and in the United States the only chemotherapeutic agents that have shown much promise in the treatment of tuberculosis have been the sulphones, streptomycin, and *p*-aminosalicylic acid. But a fourth group, the thiosemicarbazones, has now appeared on the scene from Germany, where these drugs have been developed by **Domagk** and the workers of the Farbenfabriken Bayer Laboratories at Elberfeld[6] and clinical trials have been made.

These compounds were developed through a study of the sulphonamides, sulphones, and sulphathiodiazoles, all of which show some antituberculosis activity. **Domagk** found that this activity depended not on the presence of sulphonamide or sulphone groups or thiazole or thiodiazole rings but on an open-chain arrangement of nitrogen and sulphur atoms, as in the thiosemicarbazones. Of the large number of substances tested the most active was found to be 4-acetyl-aminobenzaldehyde thiosemicarbazone,

This has been submitted to extensive clinical investigation in Germany under the names 'Conteben' and TBI-698. The sulphur atom in the thiosemicarbazones is essential for activity, and compounds derived from aldehydes are more active than those derived from ketones. The aromatic aldehydes appear to be more active than the aliphatic, and activity is increased by introducing substituents into the aromatic ring.[7] **Hoggarth** and his co-workers[8] of the I.C.I. Research Laboratories have recently examined a number of thiosemicarbazones and find that the thiosemicarbazone of *p*-ethylsulphonylbenzaldehyde is more active than TBI-698 in the mouse. TBI-698 is effective by mouth and parenterally; it is only sparingly soluble in water, but can be rendered suitable for injection by solubilising agents such as antipyrin, propylene glycol, and some acid amides. **Levaditi**,[9] at the Institut Pasteur, and **Domagk**[10] have investigated the antituberculous activity of TBI-698 in vivo. According to **Levaditi** its effect in the experimentally infected mouse is comparable to that of *p*-aminosalicylic acid, though inferior to that of streptomycin. On the other hand **Domagk** reports that in the guineapig TBI-698 is a hundred times as active as *p*-aminosalicylic acid weight for weight, and its activity is of the order of that of streptomycin. TBI-698 inhibits the growth of *Myc. tuberculosis* on an egg culture medium containing *p*-aminobenzoic acid at a dilution of 1:300,000; the comparable dilutions for *p*-aminosalicylic acid and streptomycin are 1 : 5000 and 1 : 50,000–100,000. Besides inhibiting the growth of tubercle bacilli TBI-698 produces morphological changes—abnormal size, granular disintegration, and thread formation—in the bacilli. It also changes their staining properties; the bacilli losing their capacity for taking first the Ziehl stain and then Gram's stain. The mode of action of the drug is not yet clear; it may act directly on the tubercle bacillus itself rather than indirectly via the host. **Domagk** believes that a combination of TBI-698 and streptomycin is likely to be more effective than either drug alone.

The clinical trials with TBI-698 in Germany have been reviewed by **Mertens** and **Bunge**,[11]: in 1949 **Hinshaw** and **McDermott** of the Mayo Clinic visited the various centres in Germany where the drug has been tried and they have now[12] reported their observations to the National Tuberculosis Association of America. These American workers did much of the pioneer work with the sulphones and streptomycin and so are fully aware of the pitfalls likely to arise in the clinical evaluation of new drugs in tuberculosis. Over sixty German papers on this subject have either been published or are in the press, covering observations on some 10,000 patients in more than 300 hospitals and sanatoria. The report of **Hinshaw** and **McDermott** is based on a survey of 10 of the larger German centres where TBI-698 has been in use since 1947.

The dosage of TBI-698 is much lower than that of streptomycin or *p*-aminosalicylic acid. In general an initial dose of 25–50 mg. daily for one or two weeks is suggested, with a gradual increase to 200–300 mg. if the drug is well tolerated. All observers agree that very prolonged treatment is desirable, the average recommendation being at least six months, though many patients have been treated continuously for more than a year. Unfortunately the drug has a potential toxicity which is greater in many respects than that of streptomycin. Among the minor manifestations of toxicity are anorexia, malaise, headache, and occasional vomiting; the more serious, which occurred in 4 patients per 1000, include anæmia, toxic erythema, conjunctivitis, cerebral œdema, and granulocytopenia. There is some difference of opinion on whether TBI-698 is hepatoxic; jaundice is certainly common among patients treated with it. It apparently produces a diminution in the

lobulins of the plasma and an increase in the lobulins ; since some antibodies are included among γ-globulins this is considered to be a favourable ct. The drug has a strange and deceiving action the erythrocyte-sedimentation rate. After a few s of treatment there is usually an impressive fall normal levels. This action is non-specific and ırs in patients with and without tuberculosis. The nge in sedimentation-rate in patients receiving I-698 therefore rather loses its significance as an ex of their progress.

he evaluation of any drug in the treatment of erculosis is difficult unless it can exert an impressive ct on the miliary or meningeal forms. The er clinical types wax and wane without any ific treatment. The evaluation of TBI-698 in the man cases is further complicated by the nutritional lition of the patients, many of whom were triated prisoners-of-war, at the start of treatment. eover, in many areas X-ray films were scarce paper film had to be used. It seems certain that -698 has no effect on tuberculous meningitis iliary tuberculosis, but 90–100% of the cases of ngeal tuberculosis treated have shown consider- improvement ; pain, dysphagia, and hoarseness ppear in a few days and complete healing is rved in most cases after six to eight weeks. erculous enteritis, which seems to be common German sanatoria, responds favourably, although drug has to be continued for a long time and pse may occur after its withdrawal. It should be ted out, however, that the diagnosis of tuber- us enteritis was often based on radiological ings only. Many of the patients with pulmonary erculosis were in a deplorable physical condition he start of treatment and it was very difficult to how far their improvement was the effect of d food and nursing rather than of specific chemo- apy. The German workers are enthusiastic ut the results in pulmonary patients, but HINSHAW McDERMOTT are more sceptical, though they at that the improvements are "suggestive" of e drug effect. The German and American ervers agree that the drug is most likely to have a ourable effect in fresh exudative non-destructive es of pulmonary tuberculosis, and that its action pulmonary lesions is neither as dependable nor apid as streptomycin's. In Germany the economic tor is important because TBI-698 is much cheaper l more readily procured than streptomycin or minosalicylic acid. German workers claim to have ained good results in patients with cavities by ans of local treatment and Monaldi drainage ; al treatment of tuberculous empyemas is also said be effective. In tuberculosis of the genito-urinary ct and tuberculous sinuses, fistulæ, and abscesses, NSHAW and McDERMOTT say that TBI-698 rarely dicates the tubercle bacilli completely and the ults cannot compare with those of streptomycin.

Even if we fully accept the enthusiastic German orts, there is no question of TBI-698 replacing eptomycin. Its clinical activity seems to be on a r with that of *p*-aminosalicylic acid, and its toxicity embles that of the arsenicals used in syphilis. it in spite of its toxicity it can be safely given for long riods under careful medical supervision, and the results, even on the most conservative view, call for further carefully controlled investigations. Plans are under way for the manufacture and clinical evaluation of TBI-698 in America, and trials will no doubt be conducted in this country, preferably under the auspices of the Medical Research Council and by workers who have had experience with both streptomycin and *p*-aminosalicylic acid.

Men and Women

It is no sinecure to be human ; but, even allowing for the difficulties, we cannot claim to have made much of a hand of it so far. MARGARET MEAD,[1] considering mankind anthropologically, hints that by taking thought we might do better ; and especially that men and women, as complementary partners rather than rivals, might each make a better contribution to our society. What should be man's contribution, what woman's ? We have so long thought of attributes as either male or female, so long assigned one group of tasks to men and another group to women, and so often protested when either invades the territory of the other, that few of us stop to ask what is fundamental behaviour in either sex. Miss MEAD, in an attempt to identify this fundamental behaviour—the essential differences, rather than the learnt differences, between the sexes—has compared seven Pacific peoples : the tranquil harmonious Samoans ; the prudish toiling Manus people ; the paternal altruistic undernourished Arapesh ; the laughing hating cannibal Mundugumor : the Tchambuli, among whom women are unadorned and managing, and men decorative dilettantes, and the Balinese—musical, ritualistic, incapable of enduring warmth of feeling—who have turned all life into an art.

It might be thought that we and these diverse people at least had in common the fundamental experiences of birth and suckling ; but even these can vary. True the abrupt change from the perfect comfort of the womb to the multiple troubles and discomforts of life outside is a universal experience. But it is one thing to be born in the warmth of an obstetric theatre, and to be lapped at once in cotton wool, and another to be dropped on cold wet leaves in a leaky hut and to lie there for five minutes while your mother ties the cord. The experience may differ for the sexes as well as for races ; for if, as Miss MEAD suggests, girls have keener skin sensitivity than boys, then the experience of birth in any society may be different for each sex. In other ways—from the mother's handling, from her voice—the child will early begin to learn the pattern of its own sex ; and her method of suckling it will colour its first opinion of human behaviour. The loving Arapesh suckle children tenderly. The Mundugumor women dislike both childbearing and children ; the child is never fed until he cries, and then he is made to wait. His mother stands beside him to feed him where he lies, and gives the breast grudgingly. This early struggle for the bare means of life must help to fashion this angry avid cheerful people, among whom every male is at war with every other—even with his own young sons.

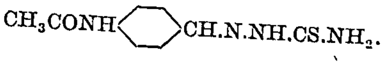
teams, 400 casualty-collection points, and 24 neuropsychiatric centres. No wonder PARK says that it is probably impossible to handle all the cases; we can only try to save some. And these grim estimates apply only to the original atomic-bomb explosions. Bombs capable of causing ten times this destruction are reputed to be a practical possibility, if not already made; and the proposed hydrogen bomb is said to be many times more powerful and destructive than even these.

Will any defence system be able to do more than rescue those at the fringe of the affected area? And if both sides in a war use these engines of obliteration, who will call himself the victor? It is of course suggested that fear of retaliation may prevent resort to atomic bombs and biological warfare.[5] But those who start wars are prepared to take risks; and it is as well that everyone should realise what is involved in the "atomic defence" of which some politicians speak so glibly.

Thiosemicarbazone in Tuberculosis

HERE and in the United States the only chemotherapeutic agents that have shown much promise in the treatment of tuberculosis have been the sulphones, streptomycin, and *p*-aminosalicylic acid. But a fourth group, the thiosemicarbazones, has now appeared on the scene from Germany, where these drugs have been developed by DOMAGK and the workers of the Farbenfabriken Bayer Laboratories at Elberfeld[6] and clinical trials have been made.

These compounds were developed through a study of the sulphonamides, sulphones, and sulphathiodiazoles, all of which show some antituberculosis activity. DOMAGK found that this activity depended not on the presence of sulphonamide or sulphone groups or thiazole or thiodiazole rings but on an open-chain arrangement of nitrogen and sulphur atoms, as in the thiosemicarbazones. Of the large number of substances tested the most active was found to be 4-acetyl-aminobenzaldehyde thiosemicarbazone,



This has been submitted to extensive clinical investigation in Germany under the names 'Conteben' and TBI-698. The sulphur atom in the thiosemicarbazones is essential for activity, and compounds derived from aldehydes are more active than those derived from ketones. The aromatic aldehydes appear to be more active than the aliphatic, and activity is increased by introducing substituents into the aromatic ring.[7] HOGGARTH and his co-workers[8] of the I.C.I. Research Laboratories have recently examined a number of thiosemicarbazones and find that the thiosemicarbazone of *p*-ethylsulphonylbenzaldehyde is more active than TBI-698 in the mouse. TBI-698 is effective by mouth and parenterally; it is only sparingly soluble in water, but can be rendered suitable for injection by solubilising agents such as antipyrin, propylene glycol, and some acid amides. LEVADITI,[9] at the Institut Pasteur, and DOMAGK[10] have investigated the antituberculous activity of TBI-698 in vivo. According to LEVADITI its effect in the experimentally infected mouse is comparable to that of *p*-aminosalicylic acid, though inferior to that of streptomycin. On the other hand DOMAGK reports that in the guineapig TBI-698 is a hundred times as active as *p*-aminosalicylic acid weight for weight, and its activity is of the order of that of streptomycin. TBI-698 inhibits the growth of *Myc. tuberculosis* on an egg culture medium containing *p*-aminobenzoic acid at a dilution of 1:300,000; the comparable dilutions for *p*-aminosalicylic acid and streptomycin are 1 : 5000 and 1 : 50,000-100,000. Besides inhibiting the growth of tubercle bacilli TBI-698 produces morphological changes—abnormal size, granular disintegration, and thread formation—in the bacilli. It also changes their staining properties; the bacilli losing their capacity for taking first the Ziehl stain and then Gram's stain. The mode of action of the drug is not yet clear; it may act directly on the tubercle bacillus itself rather than indirectly via the host. DOMAGK believes that a combination of TBI-698 and streptomycin is likely to be more effective than either drug alone.

The clinical trials with TBI-698 in Germany have been reviewed by MERTENS and BUNGE,[11]: in 1949 HINSHAW and MCDERMOTT of the Mayo Clinic visited the various centres in Germany where the drug has been tried and they have now[12] reported their observations to the National Tuberculosis Association of America. These American workers did much of the pioneer work with the sulphones and streptomycin and so are fully aware of the pitfalls likely to arise in the clinical evaluation of new drugs in tuberculosis. Over sixty German papers on this subject have either been published or are in the press, covering observations on some 10,000 patients in more than 300 hospitals and sanatoria. The report of HINSHAW and MCDERMOTT is based on a survey of 10 of the larger German centres where TBI-698 has been in use since 1947.

The dosage of TBI-698 is much lower than that of streptomycin or *p*-aminosalicylic acid. In general an initial dose of 25–50 mg. daily for one or two weeks is suggested, with a gradual increase to 200–300 mg. if the drug is well tolerated. All observers agree that very prolonged treatment is desirable, the average recommendation being at least six months, though many patients have been treated continuously for more than a year. Unfortunately the drug has a potential toxicity which is greater in many respects than that of streptomycin. Among the minor manifestations of toxicity are anorexia, malaise, headache, and occasional vomiting; the more serious, which occurred in 4 patients per 1000, include anæmia, toxic erythema, conjunctivitis, cerebral œdema, and granulocytopenia. There is some difference of opinion on whether TBI-698 is hepatotoxic; jaundice is certainly common among patients treated with it. It apparently produces a diminution in the

FAINTS AND FITS

To the public mind, fainting attacks are still a harmless sorder, whereas epilepsy still carries a stigma. Yet w much they may have in common was made clear the discussion at the Royal Society of Medicine ported on another page.

The chief differences are in onset and symptoms. In little more than half the cases a major epileptic attack gins with an aura; and unconsciousness, stiffness, d twitching follow in rapid succession. In a faint, e retina fails early, then the centres for muscle tone, and nsciousness goes next; thus the patient experiences nness of vision and loss of balance before he loses nself. Moreover he is nearly always standing; the ileptic may get his attack when he is asleep in his d. If both disorders always behaved in the classical anner, probably no confusion would arise; but, as r Charles Symonds pointed out, some 7% of fainting ople twitch or are convulsed, whereas many of those ho have epilepsy are not convulsed. Faints in childod may be supplanted by epilepsy in later years, just migraine may sometimes be exchanged for epilepsy. or the faint and the fit the essential common factor is n unstable nervous mechanism with the trigger in the ntral nervous system. Some distinguishing marks n be trusted to point to epilepsy, notably the aura, continence of urine, automatic behaviour, and perhaps rodromal yawning and biting of the tongue, but these re not always present. The electro-encephalogram ill not give a cut-and-dried answer, as Dr. Denis Williams showed. Patients who had faints only and atients who had fits only both produced bursts of fast aves, especially in the frontal lobes. But this is only say the two conditions have a common factor, not at they are identical. The waves reflect some instability the cerebral hemispheres which can be increased by arious situations and lead to unconsciousness. In pilepsy the onset is local, the site of the trouble is in the rain itself, and the spread is so rapid that the convulsion ften becomes generalised at the start.

An epileptic attack can be provoked by emotion or the ght of some feared scene (a bleeding wound, a hospital); ut so can a faint. Cerebral anæmia from whatever ause—heart-block, ventricular standstill, fall of bloodressure, or occlusion of the carotids—will produce nconsciousness. Dr. Williams disposed of the notion hat damage to the nerve-cells of the brain by anoxia night be the responsible factor in the Adams-Stokes yndrome; the loss of consciousness is too rapid to make uch an explanation plausible. He pictured the porridgy rain supported on its tree of blood-vessels: suddenly hey collapse, and the brain collapses with them—a neurogenic cause for loss of consciousness, secondary to a cardiac disaster. In either epilepsy or syncope the immediate cause of the attack may be primarily cardiovascular or primarily cerebral. With postural hypotension, a sudden fall of blood-pressure, or hæmorrhage the trouble is primarily cardiovascular; in epilepsy something goes wrong in the brain. The cardiovascular causes of loss of consciousness are legion, as Dr. Maurice Campbell was able to show; but it should be kept in mind that fainting from organic heart-disease is not common in practice. The cardiac disorders which produce it, though multiple, are relatively rare.

The crux of the discussion, as Sir Charles Symonds remarked, was Dr. Williams's new concept that some people are more liable to lose consciousness than others, whether from epilepsy or not. This view of things, if generally disseminated, might do much to make life easier for epileptics.

SIGNIFICANCE OF A RISE IN SERUM-AMYLASE

THE estimation of serum-amylase deserves a large place in the diagnosis of acute pancreatitis, for a normal level rules out this disorder while a very high level confirms its presence. A moderate rise may be found when the pancreas becomes involved in an adjacent pathological process, and sometimes in cases of acute inflammation of the salivary glands or renal failure. To these causes Musgrove,[1] of the Mayo Clinic, has now added a fourth—free perforation of gastroduodenal lesions, with liberation into the peritoneal cavity of pancreatic amylase which is subsequently absorbed.

During 1948 the emergency surgical service at the Mayo Clinic dealt with three cases in which the serum-amylase levels were raised but the pancreas was subsequently found to be normal. These cases all had a perforation high up in the gastro-intestinal tract and severe generalised peritonitis. Musgrove concludes that when a large free perforation of a peptic ulcer occurs during the phase of active digestion, a large amount of gastroduodenal chyme may be poured out into the peritoneal cavity and the subsequent absorption of pancreatic amylase will cause a moderate rise in the serum-amylase. This supposition has been confirmed experimentally by Pemberton et al.[2] Of 14 dogs with anterior perforations of the duodenum, they found 4, all of which had eaten a large meal 1–2 hours before perforation, with high amylase values both in serum and in the peritoneal fluid. The amylase content of their peritoneal fluid, expressed in arbitrary units based on the number of mg. of maltose liberated by the amylase present in 1 ml. of fluid, was 130–352 units. The other 10 dogs, which had no rise of serum-amylase after perforation, had eaten their last meal 2–3 hours before perforation, and their peritoneal fluids contained only 23–58 arbitrary units of amylase per ml.—a sixth of the amount in the 4 animals. When the interval between the last meal and perforation was more than 3 hours the serum-amylase never rose; when the interval was about 2 hours the level was raised a little; and when the interval was only an hour or so there was always a distinct rise. The site of perforation apparently did not influence the subsequent behaviour of the serum-amylase. In normal dogs, the intraperitoneal administration of amylase produced a prompt, well-marked, and long-continued rise in serum-amylase. Further experiments showed that an associated pancreatitis or peritonitis had no appreciable effect on the post-perforation serum-amylase level. In 2 dogs with a persistently patent ulcer there was no rise in serum-amylase in the early hours after a perforation; but the level was high at 70 hours after perforation. The explanation of this

[2] Pemberton, A. H., Grindlay, J. H., Bollman, J. L. *Ibid*, p. 5.

In lightly clad societies the bodies of males and females are taken for granted. The small Balinese girl early learns that she is female, and has only to *wait to become a mother*; *and the boy accepts this* as something she will achieve which he never can. The girl child in our own civilisation has no such certainty, nor does the boy usually think of her as a potential mother; he is far more likely to regard her as an incomplete and partial male—as she is also apt to regard herself. "The difference between the sexes that is forced home on children in our world of walled-in self-contained flats," as Miss MEAD says, has to do with differences in occupation, in dress, in privilege. All women do not have babies, but most men don't have to wash dishes." (That, of course, is in America.) In some of the Pacific societies, however, appreciation of women's childbearing capacity goes very deep as a cause of envy to the other sex—envy expressed in initiation ceremonies at which adolescent boys are reborn symbolically of men, not of women.

The outward manifestations of sex—the deep voice, hairy chest, great height, or heavy musculature which some societies regard as manly, and the big breasts (*or conversely the small high breasts*) which are felt to be particularly womanly—are not directly related to fertility. Differences in appearance—between the large "manly" man and the small rabbity man, the billowing "motherly" woman and the boyish girl—are differences not in reproductivity but in biological type. The small rabbity man is quite often more fertile than the large muscular one; and if he had been bred among a people, like the Arapesh, where men are small, kindly, and unassuming, nobody would have questioned his manliness. Small breasts lactate as well as, and sometimes better than, heavy ones: one type is not more essentially feminine than the other. We might gain, Miss MEAD thinks, by recognising that among our own people—or anyhow among Americans, for whom she is primarily writing—there are many biological types. We should then cease to expect all men and women to conform to standard types of behaviour or to follow a rigid set of occupations. The boy with *artistic leanings would not be suspected of effeminacy*, and the girl who shows a greater need to take things apart than most other little girls would not be reproached. "In such a world," says Miss MEAD, "no child would be forced to deny its sex membership because it was shorter or taller, or thinner or plumper, less hairy or more hairy, than another, nor would any child have to pay with a loss of its sex membership for the special gifts that made it, though a boy, have a delicate sense of touch, or, though a girl, ride a horse with fierce sureness."

Applying her method of observation *and deduction* to her own people, Miss MEAD reminds us how many cultures have gone to the making of Americans. They have no single traditional pattern to follow, no small closed tribe hedged and comforted by customs. "Every home is different from every other home, every marriage, even within the same class, in the same clique, contains contrasts between the partners as superficially striking as the difference between one New Guinea tribe and another." Even in America, however, there are some patterns of behaviour which mould the child. Boys and girls are consistently urged towards success—urged to *make good, get on*, be happy, be fulfilled, be the ideal. Some feel keenly the discrepancy between *the real and the ideal, asking themselves* "Am I getting on enough?" or "Am I as happy as I ought to be?" In adolescence they have to learn the exigent routine of "dating." To be a good date—popular and sought after by your own set—is to be a success. *To choose to be solitary when you have* been asked to go out is to be selfish and lacking in good sportsmanship. "Petting" is almost another duty, in which the boy is expected to ask more than he hopes to be granted, and the girl is expected to refuse him—capably, gaily, and with poise. This in itself has unforeseen effects later, when the young people finally seek permanent mates; for the girls have acquired in this exacting game a degree of self-control which makes it hard for them to surrender fully as wives. Easy divorce, strangely enough has added another anxiety to life; for it has become a duty to free the other partner if he or she wishes to be freed, and many a conscientious couple endure such self-questioning as "Ought I to give him a divorce?" "Would he develop more with someone else?" "Would she be happier if she were free?" Every quarrel becomes a prospective rupture, every day renews their solicitous care for the marriage relationship, lest it grow too brittle to hold together. There are good points about this, of course, but it seems a hard way of doing it compared with the older method of marrying for good with no except through a destructive scandal. However, there is no going back to former patterns; and Miss MEAD hopes that such things as marriage counsellors, nursery schools, and housekeeping services may ease the strain on young married couples and help them to keep together with less emotional tension.

It is impossible to pack into a nutshell the trunk, spreading branches, and innumerable little twigs of this vast tree of Miss MEAD's book; but it is clear from all she says that American society—and ours too in equally well-defined ways—has not produced the pattern in which both sexes can make, easily and generously, their full contribution. Boys *are made jealous and resentful of girls, girls are made* envious of boys—a useless rivalry which every generation perpetuates afresh. In seeking the fundamentals of human behaviour she has found a permanent pattern: in all known human societies there is some form of the family; and it is distinguished from the families of other primates by the fact that the male helps to provide food for the females and children. Inside this simple pattern there is room for both sexes to live constructively as colleagues sharing a task. She outlines the *generally rather than specifically. Our* mistakes at least are clear.

> "Either sex may be distorted by the presence of the other sex, or it may be given a fuller sense of sex membership. . . . If parents define one child as less complete, less potentially gifted, with less right to be free, less claim to love and protection, or less a source of pride to themselves than the other, the child of that sex will, in many cases, feel envy. If society defines each sex as having inalienable qualities of its own but does not relate those qualities to the reproductive differences between the sexes, then each sex may be proud and strong, but some of the values that come from sex contrast will be lacking. . . . Externally

some given period of history and in some set of social arrangements it may often look as if one sex gained and the other lost, but such gains and losses must in the end be temporary. To the extent that women are denied the right use of their minds, their sons suffer as well as their daughters. . . . If our analysis s deep enough and our time perspective long enough, f we hold in mind all the various possibilities that other cultures hint at or fully embody, it is possible o say that to the extent that either sex is disadvantaged the whole culture is poorer, and the sex hat, superficially, inherits the earth, inherits only a very partial legacy.”

The implicit conclusion—that sex rivalry is not fundamental characteristic of human behaviour t a learnt pattern, and that if one sex wins both e—is the heart of a book alive with promising ions. It should indeed be possible, by taking ought, to do better.

SIGNIFICANCE OF A RISE IN SERUM-AMYLASE

THE estimation of serum-amylase deserves a large place in the diagnosis of acute pancreatitis, for a normal level rules out this disorder while a very high level confirms its presence. A moderate rise may be found when the pancreas becomes involved in an adjacent pathological process, and sometimes in cases of acute inflammation of the salivary glands or renal failure. To these causes Musgrove,[1] of the Mayo Clinic, has now added a fourth—free perforation of gastroduodenal lesions, with liberation into the peritoneal cavity of pancreatic amylase which is subsequently absorbed.

During 1948 the emergency surgical service at the Mayo Clinic dealt with three cases in which the serum-amylase levels were raised but the pancreas was subsequently found to be normal. These cases all had a perforation high up in the gastro-intestinal tract and severe generalised peritonitis. Musgrove concludes that when a large free perforation of a peptic ulcer occurs during the phase of active digestion, a large amount of gastroduodenal chyme may be poured out into the peritoneal cavity and the subsequent absorption of pancreatic amylase will cause a moderate rise in the serum-amylase. This supposition has been confirmed experimentally by Pemberton et al.[2] Of 14 dogs with anterior perforations of the duodenum, they found 4, all of which had eaten a large meal 1–2 hours before perforation, with high amylase values both in serum and in the peritoneal fluid. The amylase content of their peritoneal fluid, expressed in arbitrary units based on the number of mg. of maltose liberated by the amylase present in 1 ml. of fluid, was 130–352 units. The other 10 dogs, which had no rise of serum-amylase after perforation, had eaten their last meal 2–3 hours before perforation, and their peritoneal fluids contained only 23–58 arbitrary units of amylase per ml.—a sixth of the amount in the 4 animals. When the interval between the last meal and perforation was more than 3 hours the serum-amylase never rose; when the interval was about 2 hours the level was raised a little; and when the interval was only an hour or so there was always a distinct rise. The site of perforation apparently did not influence the subsequent behaviour of the serum-amylase. In normal dogs, the intraperitoneal administration of amylase produced a prompt, well-marked, and long-continued rise in serum-amylase. Further experiments showed that an associated pancreatitis or peritonitis had no appreciable effect on the post-perforation serum-amylase level. In 2 dogs with a persistently patent ulcer there was no rise in serum-amylase in the early hours after a perforation; but the level was high at 70 hours after perforation. The explanation of this finding is that the pancreas goes on secreting amylase into the duodenum after a duodenal perforation; so if the perforation remains open there will be a continued flow into the peritoneal cavity and hence, by absorption, into the blood-stream. Clinically, therefore, a persistently raised serum-amylase level might indicate patency of a perforation and a guarded prognosis.

TRACER STUDY OF SPINAL ANÆSTHESIA

WHAT happens to a spinal anæsthetic after its injection has been only partly revealed by the methods of investigation hitherto used. Recently, however, the radioactive tracer has been brought to bear on this problem by Howarth and Cooper,[1] of Manchester University, and Howarth has elsewhere[2] described how procaine was made radioactive by the *introduction of Br^{82} into its molecule.* The spinal-anæsthetic properties of the radioactive dibromoprocaine (D.B.P.) thus obtained was investigated in cats, and both its potency and its lack of toxicity were established. A satisfactory method of radio-assay was evolved, and finally a study made of the fate of the brominated benzene rings of the injected D.B.P. The brominated procaine contents of cerebrospinal fluid, blood, and urine were estimated at short intervals. It was found that D.B.P. rapidly leaves the theca and appears in the urine in high concentration while maintaining a persistently low blood-level. Of the body tissues, only the spinal roots showed consistent capacity to concentrate the drug above the level in the cerebrospinal fluid at the site of injection; and only the kidney and liver appeared to concentrate D.B.P. above the level in the circulating blood. It seemed, too, that so far as the cat is concerned the veins are the main route of departure of this anæsthetic from the spinal theca.[1]

LATENT PROSTATIC CANCER

THAT carcinoma of the prostate is quite commonly latent has been confirmed by Andrews,[3] who has found cancers in 17 (12%) of 142 prostates removed at necropsy from males aged 15–79 years in whom prostatic carcinoma had not been diagnosed clinically or on gross examination at necropsy. Sections at roughly 4 mm. intervals were examined and the diagnosis of malignancy was based on the presence of abnormal stromal relationship plus any three of the following: nuclear changes, mitotic figures, anaplasia, heteroplasia, lymphatic invasion, and invasion of the blood-vessels. All the cancers were in men over 40; the incidence rose significantly between the sixth and seventh decades but not beyond the seventh—which runs counter *to Moore's*[4] *observation that the* incidence increased steadily up to a maximum at the ninth decade. In one case the tumour was so extensive that its site could not be determined (this was the only gland where the middle lobe was involved and the seminal vesicles were infiltrated). In 4 glands two separate areas of carcinoma were found; in 2 of these there was a well-marked difference in the size of the tumours, but in the other 2 the tumours were of much the same size, supporting the view *that prostatic carcinoma may* be multifocal in origin.[4] Among the 20 small growths that could be localised with fair accuracy, 12 were confined to, or affected chiefly, the posterior lobe, while 8 arose in the lateral lobes; 11 tumours in the posterior lobe and 2 in the lateral lobes arose just beneath the capsule, and in 8 of these the capsule was infiltrated. The tumours were all adenocarcinomas, composed mainly of small acini. In 15 of the 17 affected prostates perineural lymphatic *invasion* was present, and in 5 this was extensive; "it was often remarkable that the perineural lymphatics were invaded by the most differentiated acini in the tumour." Invasion of blood-vessels was not common. Andrews describes a characteristic precancerous hyperplasia, affecting not only carcinomatous glands but also normal glands, and particularly those with benign hypertrophy; and benign hypertrophy, he remarks, is closely associated with latent carcinoma.

This high incidence of microscopic carcinoma in the prostate is puzzling; but, as Andrews points out, the prostate is of a convenient size for the thorough microscopical examination needed to detect such growths; and an unexpectedly large incidence might be found in other organs submitted to a similarly careful search.

"CHEMOCRACY"

CAN chemistry help to provide enough food for the world's growing millions? In a striking article, published in the U.S.A., Rosin[1] replies with an emphatic Yes. He goes further, believing that if we apply our minds to the synthesis of foodstuffs, agriculture can disappear. "The result will be the greatest revolution in the history of mankind since the time man learned how to make fire."

Throughout recorded history man has depended on *the soil for his very life; and the natural impulse is to* dismiss such a revolution as a flight of fancy. But is it?

> "The slow process of replacement of agriculture by *chemical industry started* about 80 years ago with the synthesis of alizarin (in 1868) and indigo (in 1870).... Other victories of chemistry over agriculture followed in swift succession. Synthetic dyes, textiles, drugs, vitamins, cosmetics, and food products replaced their natural counterparts."

Among the most recent advances is the manufacture of synthetic rubber by the improved "cold" process developed last year, which is claimed to be both better and cheaper than the natural product; and "*there can* be no valid reason to assume that the rest of the natural products, including foodstuffs, could not be equally synthesised." As to foodstuffs, when the last secrets of photosynthesis are penetrated, the behaviour of plants may be imitated in factories; and it is noteworthy that at the University of Chicago C^{14} has helped to disclose the hitherto unknown intermediates in the transformation of carbon dioxide into sugar and starch by chlorophyll. Sugar and starch, Rosin believes, may be produced by polymerisation, with formaldehyde as raw material. Similarly synthetic fat and protein is not beyond the chemist's reach; and even taste can be added artificially *or reinforced by sodium glutamate, which, without being* a flavour is said to be "the substance that makes food taste in the expected way."[2]

Our dependence on the plant in producing food represents a double bondage: first, in terms of man-power, for more than half of all the available man-power of the world is engaged in agriculture; and secondly, in terms of space, agriculture taking up 4 billion acres—of the habitable part of this planet. Raising the efficiency of agriculture by various chemical means may well stave off starvation from the 3000 million people who are expected to inhabit the earth at the end of this century, or the 4000 million seventy years from now. "However, we do not want our children merely to be saved from starvation, we want them to have an actual abundance of food."

THE death is announced of Dr. R. P. RANKEN LYLE, emeritus professor of midwifery and gynæcology in the University of Durham.

Dr. L. HADEN HADEN-GUEST has taken the name, style and title of Baron Haden-Guest, of Saling in the county of Essex.

Points of View

IE SOCIAL SIGNIFICANCE OF SYMPTOMS

WILLIAM GOODDY
M.D. Lond., M.R.C.P.
GISTRAR, NATIONAL HOSPITAL, QUEEN SQUARE, LONDON

N this “ age of the common man,” the employment of nptoms has become part of the everyday technique ocial existence. Security has become the prerogative ts all, and much of it is administered through medical nnels. The public are repeatedly reminded of this npulsory provision of welfare, and many people have been slow to realise that by trading upon the good ure, uncertainty, and fatigue of those employed in medical and ancillary services, they can avoid esired consequences of their actions and circumnces. By claiming symptoms of diseases from which y do not suffer, they can obtain the same sympathy concessions as would be their right if in fact they these diseases. Thus the idle and improvident make d their losses and the criminal escape their punishment.

here are signs that this process is spreading, and will tinue to spread, with increasing speed. It is the ect of this article to discuss the nature, causes, and itment of the ill effects that are likely to ensue.

he question is by no means of purely academic or lical interest. Recent statements of a judge on the rce ” of the death penalty, and of a bishop on the enic aspects of physical and mental defect, show t a problem of general importance is raised. It is now evident that the original financial estimates the National Health Service quite inadequately ssed the cost of managing the total problem of the ion's health. But we are not concerned here with the or and probably self-adjusting difficulties over tacles, dentures, and wigs, nor with the great cost nvestigations, medicines, and administration for the te and chronic sick. There is nothing strange nor easonable in them. It is towards the dangerous tenncy to place the incapable, the ineffective, and the rupt in positions of power, responsibility, or material afort that our attention must be directed. Unless are alert to this trend we shall penalise those of ater strength and merit who disdain to avail themves of facilities which they feel are to be obtained by aggeration or deception. If we make things comfortle, happy, and “ soft ” for everyone, regardless of eir characteristics, we shall weaken our national ity ; for we cannot do these things at present without noving the necessary rations of ease and satisfaction m people who have deserved them.

I do not, of course, mean to criticise the conduct or atment of those who are truly sick in body or mind, to reflect on the humane advances of psychiatry in ent years—though these advances may provoke the estion as to how one can tell just who is sick and who not. I am, indeed, clear that there is no excuse for glecting psychosomatic disorders, and that harsh atment of neurosis shows a defect in the physician. et how much more severe than a whipping from a hoolmaster or a few brisk words from the doctor are, r example, electroconvulsive therapy and leucotomy. l in all, as much harm is done in pronouncing illness esent when none exists, as in declaring established sease absent.

Some authorities urge that if a patient is unhappy nd has symptoms of ill health in surroundings which re distasteful, such as a dull job with low wages, but is ontent and symptom-free when transferred to a conenial occupation with a good wage, cure consists in roviding him as nearly as possible with what he wants. his might be true if it were possible for everyone to have, all their lives, an easy job with a large salary. But these ideal conditions are still only suggestions of what the future may provide. We do not live in the Utopia of Thomas More, nor in the community of the Abbey of Thélème described in 1532 by the physician, Rabelais, where :

> “ All their life was spent not in laws, statutes, or rules but according to their own free will and pleasure. They rose out of their beds when they thought good ; they did eat, drink, labour, sleep, when they had a mind to it, and were disposed for it. None did awake them, none did offer to constrain them to eat, drink, nor to do any other thing. In all their rule, and strictest tie of their order, there was but this one clause to be observed. DO WHAT THOU WILT. Because men that are free, well-born, well-bred, and conversant in honest companies, have naturally an instinct and spur that prompteth them unto virtuous actions.”[1]

Good working conditions and wages have been won in the past by those who have, from their talent or industry, shown themselves suitable for them. The system now being substituted will reserve for the weak and lazy the jobs which they are least well equipped to hold, and the normal will be expected to carry on in the more arduous and unprofitable tasks until they too succumb to what in this era of neologisms may be termed “ sociosomatic disease.”

THE CLINICAL PROBLEM

This subject first presented itself to me during service with the Armed Forces in the late war ; but there can be few who practise medicine nowadays who have not been faced with the blackmail of gastritis, fibrositis, blackouts, dizzy turns, or like diagnoses, some with names from the *Nomenclature of Diseases* and others either picturesque ideas of the patient, or the Latin or Greek equivalent for the symptom which the patient has presented.

Any attempt to analyse these symptoms releases vivid descriptions—“ unbearable,” “ like a knife being driven in,” “ like blows from a hammer.” Two actual but more elaborate descriptions recently heard are “ like broken glass in my stomach ” and “as if the top of my head was open and someone was pouring cold water into it.” They differ much from the story of the patient with unequivocal disease, for he usually says that, never having had anything like his symptoms before, he cannot describe them. He generally notes either pain or an indescribable abnormality.

In describing psychogenic headache Walshe[2] writes :

> They are described in a wealth of metaphor, and by a lavish use of superlatives. Thus, they are “ terrible,” “ agonising,” “ frightful,” they are like corkscrews, knives, needles, &c., piercing the head. When questions as to their locality and quality are pressed, the patients' answers become ever more florid and vague, and “ pains ” are suddenly found to have become sensations of weight, pressure, or constriction and not real pain at all. . . . It is not information that these patients wish to convey but an impression that they wish to create.

No-one will deny that gastritis or blackouts do exist as accompaniments of demonstrable disease, such as peptic ulcer and alcoholism, or cerebral tumour and idiopathic epilepsy ; but often there are no findings to suggest such conditions. If, for example, the sufferer from blackouts is fully investigated, a detailed history provides a vague changing account of the attacks, with a retreat from “ passing out ” to dizziness and giddiness. These last two are then explained as “ everything goes black so that I fall down.” When the patient is asked why he adds to his troubles by falling instead of

standing still until he is better, he may state that after all he doesn't "really remember what happens." Without difficulty it is elicited that adverse stress such as conscription, change of job, or an amatory setback (often precipitated by seeing a romantic cinema programme) was followed either at once or in a few days by spells of lost memory or consciousness, with falling and dramatic episodes of fighting and weeping. In the past perhaps such symptoms have caused release from other difficulties. The patient claims as proof of his organic disability: "I was released from the pits through these attacks and the doctor said it was my nerves." Yet he may admit to having earned, since then, an agreeable number of pounds a week as a driver, welder, stoker, or circular-saw operator. Personal details may show a bad family and educational background, with a lack of general and unselfish interests and hobbies, and an avoidance of organised games.

General examination in detail is negative for structural disease, though poor physical and mental development are often but not always found. Further tests—more specialised, expensive, and elaborate—are done so that no reasonable doubt is left in the exclusion of gross disease. The carotid sinus is compressed. The blood Wassermann reaction and sugar levels, fasting or after glucose administration, are requested. The cerebrospinal fluid may be tested. The skull is X-rayed and an otologist's examination carried out. If possible an electro-encephalogram is also done. Negative results are obtained throughout. A diagnosis of hysteria, syncope, or anxiety state may be made. It is rare to have available an authoritative opinion that no medical disability can be found, for most of these patients do not reach such high levels, and again it is not always possible to have the careful investigations I have mentioned. Malingering does cross the mind; but, by common consent, as being incapable of proof and from a feeling that some "psychosomatic dysfunction" may be neglected, it is dismissed.

Symptoms referable to the cardiovascular, respiratory, locomotor, and alimentary systems may be similarly studied with all possible care at the expense of much time, money, and frank annoyance. "Tired" and "weak" hearts, "gastritis," "gastric stomachs," "fibrositis," "bronchial trouble," and "nerves" are commonly encountered. The patients circulate from department to department, from the cardiologist to the neurologist, from the orthopædic clinic to the psychiatric, from the gastro-enterologist to the gynæcologist. They may change in secrecy from one competent hospital to another where the whole process is started again. This sort of patient has a high nuisance value which weighs upon his examiner even before he enters the room. He will claim that he has made an appointment by telephone but none of the staff can recall the conversation and he does not know to whom he spoke. A large set of notes in which the relevant details are deeply embedded may precede him, or he will say that he has no idea of the nature and results of investigations carried out elsewhere. He will agitate if kept waiting, will smoke beneath a "No Smoking" notice, and have such an attitude of grievance and "the world owes me a living" that the doctor quails before him, seeking not a diagnosis but a means of getting rid of him. We think up a remedy he may not have tried, or another investigation which might with decency be done and promise to see him in a month's time or write to his doctor. In all the practice of medicine, self-seeking is the rarest of diagnoses. Not infrequently a patient, being dissatisfied with one, two, or even three clinics in London seeks fresh advice at a fourth. X-ray and laboratory tests are done each time, as often as not; for what gastro-enterologist will rely on the X-ray findings of a general physician, and what neuroradiologist will accept the plates of an orthopædic department?

Eventually labels—which today are essential [illegible] "documentation," medical registers, disease indexes, and especially for certificates—are attached to the patients by the methods I have described, and decisions or recommendations are made about employment, discipline, change of locality or diet, preferential housing conditions, or other comforts in respect of which someone else necessarily goes short.

For example, a corporal in the R.A.S.C., seen during the war, stated that he vomited the food supplied at his unit. He had been given a home service category for chronic gastritis (though he had been shown to have no disease of the stomach after two separate periods in hospital with two X-ray examinations, including screening and barium meal), so that he could live at home, on civilian rations with his wife to cook for him. In these circumstances he was willing to do a day's work, but should his unit be moved he was within a few days back in hospital "for investigation and treatment please" because "he vomits everything he eats."

Other glaring examples from Service conditions have been provided by some men at the time of their release. Early in his army career a man may have been downgraded for a disability such as flat-foot or anxiety state. He may thus have avoided marching, guard duties, and physical training or overseas service. On demobilisation he plans to become a policeman, or a civilian government official abroad, with better living conditions than he has been used to in the United Kingdom. He therefore asks to be upgraded, because his disability "no longer causes me any bother and might be awkward when applying for this job I want."

In the Services during war it was essential to [illegible] any who were liable to break down and impair the [illegible] of their unit. In all those conditions for which [illegible] physical basis had been found, it became the [illegible] for the psychiatrists' department to dispose [illegible] patient, and special powers were given them for [illegible] so. Invaluable work was thus done; but there [illegible] corresponding disposal now that the war is over; [illegible] even if there were, there are not enough psychiatrists to undertake it. The necessary duty of discharging [illegible] fits and nuisances from the Forces was often done, not because the psychiatrist thought the man in any [illegible] ill, but because he felt that he would be more trouble [illegible] the Service than he was worth. In peace-time the short-term policy forced on the fighting units will not be satisfactory, and more doctors will have to be their own psychiatrists—as many have been for years—instead of referring their tiresome patients to the nearest psychiatric centre.

Nowadays for many doctors the war-time problems have fallen into the background, but there are still [illegible] numbers of patients to whom Service medicine pointed the way to skilful employment of symptoms in [illegible] life. The discharge as medically unfit was a temporary measure of expedience, and solved few long-term problems. Commonly such a discharge carried with it a pension, or a grudge for the failure to get one. [illegible] the first case there is a natural inclination to keep [illegible] any disability which brings in money. In the second there is a lifelong indisposition, often accompanied by a most expensive, laborious, and repetitious [illegible] tion of "justice," "rights," and "fair play" which [illegible] shared at one time or another by the majority of [illegible] tioners both inside and out of hospital, in addition to various welfare organisations which include legal [illegible] and often expect free medical pronouncements in their clients' favour.

The purely civilian counterpart is that intractable ailment the "compensation neurosis." We must [illegible] forget too, how often medical opinions are invoked in the law-courts to excuse antisocial activities. Murder, theft, and financial default are attributed to brain-storms or alleged to occur during a loss of memory often conflicting evidence of psychiatrist and rologist causes much public mistrust and uncertainty.

he situation is difficult and complicated; nor is it ·d by the recent advances in social welfare in so far ,hey are not accompanied by a recognition that the rovements involve responsibilities for those who)y them—negatively, not to abuse the new privileges, positively, to offer a personal contribution, by urance and industry, to the maintenance of good ıdards.

, is reasonable to use the working model of the :es medical services for observing the benefits and ; of a comprehensive health service, because many ciples are common to both. But our National Health ·ice is, firstly, far larger than its model and therefore ; far more slowly. Small but important abuses will efore be noted less quickly and clearly. Secondly, e is no "discharge as medically unfit" from civilian until:

"Thou thy worldly task hast done,
Home art gone, and ta'en thy wages;"

THE SOCIAL PROBLEM

ı any attempt at "treatment and disposal" it is ntial to discover the causes of the disability. They divided between patient and doctor.

he largest single factor in the patient is derived from inborn and acquired defects of human equipment, ·ate and public, over which a man may have little ·trol and for which he is largely blameless. He may of a family which has a poor mental and physical ord, and may have been constitutionally at a dis-antage from his earliest days. We must acknow-e also, besides these hereditary factors, defective cation and inadequate social opportunity, from erty or unemployment. Yet more vital as factors he present moment are the effects of lack of proper sing. Many patients seek medical advice for symp-ıs which are due to failure to secure privacy, quiet, uty, or comfort in their homes. A headache is a son, indefinitely extendable, for a note to the housing hority. But all these are social and eugenic problems do not directly belong to the practising physician or geon in his daily work. It is not possible for the lical profession to act on behalf of each patient in se matters: it can do no more than advise general nciples in those vitally important aspects of civilisa-ı. We all are aware that dirt and poverty, ignorance l slums, contribute grossly to disease; but we cannot ke each patient who enters an outpatient department ın, rich, educated at a public school, and housed in a vice flat.

'or the patient, something for nothing has always 'n an attractive proposition, and the successful ımples of others in ameliorating their public and vate circumstances by the manipulation of symptoms ve been easy to copy. Their small suspected or agined defects are magnified by advertisements which lect fear from every paper and poster. No town-eller travels to his job without visible insinuation that has a vitamin deficiency, that he is certain to have a d, that he must expect headache, and that his hair 'alling out. He is a prey to the spectres of mortality, aster, and enfeeblement which urge him to insure nself and his estate. Minor disabilities which should ve passed unnoticed are enlarged upon. It is but a ort step to their elaboration into an oppressive symptom mplex which can be used to gain relief from the cessity to struggle for existence.

The faults of the doctor are perhaps equal to those of e patient; for the patient is, after all, playing him his own game. They result mostly from failure to make ı exact diagnosis. The usual reasons given for inability to give a diagnosis are lack of time and lack of facilities for investigation. The first reason is only partly valid, for a clear statement of the lack of discoverable disease and an undertaking to review the case after a suitable interval, so that nothing shall be missed, takes less time and energy than the repeated periods spent listening to a story which neither doctor nor patient fully believes, as each new social emergency arises. In answer to the second reason we know that accessory means to diagnosis are now widely available. The type of patient now under consideration has usually been investigated more, not less, than is necessary.

A further obstacle to a confident statement of normality is the risk of being caught out by rarities, such as the carcinoma in the twenties or one of the new syndromes from the medical journals. One may be obliged to assess imponderables such as the proportion of organic damage to neurosis after head injury—and we are ever prey to our own prejudices and to the value-judgments of our own social standards. These hazards, and the fear of criticism, litigation, and failure, are always in the mind, weakening our attempts to separate the ill from the feigning ill. The weapon of the socially sick is the phrase "I am not satisfied," and it is wielded mercilessly and without consideration of the potential danger to its wielder. Most doctors are trained in the belief that satisfaction, which amounts to a panacea for all the strains of daily existence for the patient, is in their power to select or devise and then administer. This belief is untrue and misleading. It betrays a foolish pride. However anxious we are to do our best, we should not be satisfied to think our remedy consists in providing for all and sundry an escape which each time drains still more the reservoirs of social security.

MANAGEMENT OF SOCIAL SYMPTOMS

The solution of the problem lies in assessing the validity of symptoms and in not permitting symptoms to go uncriticised; and this will be a long, slow and laborious process. To find it we must be well aware of the dangers, expense, and annoyance of false diagnosis. There must be a careful assessment of each patient as a whole, with special reference to past conduct, family pattern, and social habits. This must be followed by a complete examination and all relevant investigations required to exclude active disease. At the end of these it should be possible to know whether structural disease or a psychopathological process underlies the symptoms. For each there is an appropriate line of treatment. Should the honest conclusion be that neither of these exists, it is our duty to say so, however unpleasant or inconvenient it may be. We may point out social causes for symptoms, explain where the remedy lies, and offer a real sympathy; but we may not shoulder those particular burdens, nor accept responsibility for them. Though most doctors are genuinely distressed by altercations and scenes with their patients and wish to avoid them, it is useless to get the patient out of the consulting-room by giving him a bottle of medicine or the promise of an X-ray examination instead of a candid statement that nothing wrong has been found and that the required certificate or desired recommendation therefore cannot honestly be given on medical grounds. Once a nuisance concession or medical pronouncement on symptoms of social origin is made it can hardly be rescinded.

CONCLUSION

Symptoms are being used by some patients as reasons to persuade members of the medical profession to interfere in social matters.

In so far as we fail, after proper deliberation, to state firmly our disbelief in any symptoms which we do not consider primarily due to a disease process, we weaken our authority, decrease our personal honesty, and sow the seeds of much difficulty and unpleasantness, the fruits of which must one day be gathered.

Symptoms should be used as aids to diagnosis of disease and not as final reasons for medical judgment.

A more robust and critical approach, based on sound diagnostic methods, is required to meet the problems of patients in our present social structure.

I am most grateful to Dr. F. M. R. Walshe, F.R.S., for his kind criticism and advice in the presentation of this paper.

Disabilities

45. CROHN'S DISEASE

I AM now 26 and have suffered from Crohn's disease since early adolescence. The symptoms suddenly became severe 7 years ago and a palpable mass was discovered in the right iliac fossa. The lesion was confirmed at operation and a one-stage right hemicolectomy was performed. For 2 years after this I enjoyed the luxury of an unprotesting digestive tract, and was a "clinical cure." Alas, I now belong to the small group of cases which recur after surgical treatment. Symptoms and signs, indicating a partial obstruction proximal to the anastomosis between ileum and transverse colon, returned insidiously over a period of 9 months. I was readmitted to hospital and for several months underwent extensive investigation and observation. It was eventually decided that the disease was no longer progressing and could be controlled without further surgical treatment. In Crohn's disease there is always a chance of eventual recovery if the pathological process can be kept in check. Such is my hope for the future.

* * *

My outstanding symptom has been pain, of two distinct types. The more frequent type is hard to describe. It consists of more or less continuous abdominal discomfort, not localised to any particular quadrant, and often passing through to the back. This is a dull constant pain, never severe enough to be totally incapacitating. Sometimes the abdominal muscles are tender and the abdomen visibly distended, making it difficult to fasten the top trousers-button. This pain is relieved by firm manual pressure, and though it does not prevent me from continuing with my work it lessens efficiency and tries the temper, so that at times my patients, friends, or relations probably think I'd be better dead or certified! Excessive smoking makes this symptom worse, perhaps by some effect of the constituents of tobacco or perhaps because of the concomitant swallowing of air.

The second pain is quite different. It is violent while it lasts, completely disabling, and obviously a true colic, cycles of pain occurring in a crescendo-diminuendo fashion every few minutes. The pain is usually felt centrally in the abdomen. Each attack lasts from 2 to 12 hours and is accompanied by vomiting and an intense agony of mind. Erection of the bowel can be felt with each cycle of pain and at times there is visible peristalsis. Warning of an attack is given by the bowels not opening at their usual 4–6 hourly intervals, especially if this "constipation" is accompanied by turbulent borborygmi. The cessation of an attack is always heralded by severe diarrhœa.

Rightly or wrongly, I have interpreted the two pain patterns as being due to different mechanisms, and have planned treatment accordingly. That this plan has been sound is shown by the fact that five years ago, when my recurrence began, I looked like developing into a chronic invalid, being persistently troubled with the first variety of pain and having attacks of the second as often as twice a week, whereas now I can do active medical work with virtually no disability.

The first, less severe type of pain, I look on as a result of impaired digestion of all major food constituents. Failure to absorb fats is a well-known feature of Crohn's disease. I think that in my case the digestion of carbohydrate and protein is also impaired and that this pain arises from distension of the small bowel by gaseous products of the consequent fermentation and putrefaction. That steatorrhœa was not the sole factor was shown by the observation that exclusion of fats from the diet did not eliminate this pain, though complete starvation definitely abolished it. I try to compensate for the impaired digestion by taking two or three compound 'Taka-Diastase,' pepsin, and pancreatin tablets with each meal. The effect has been most gratifying, and I am now little troubled by this pain. I never wear tight belts or bands round my waist, because they aggravate the discomfort of any distension which occurs.

I interpret the second type of pain as a symptom of temporary obstruction at the site of recurrence of the disease. The attacks almost invariably follow a dietary indiscretion. Over the years I have compiled a mental list of foods that I can safely eat. Anything that leaves much residue and might therefore cause obstruction is excluded. This means no green vegetables, fresh or dried fruit, or in fact any foods with pips, skins, or coarse fibres. I never even take purées. My diet consists mainly of meat, fish, and stale bread, garnished with eggs, cheese, and milk, and I have frequent small meals. Such a diet, besides being low in residue, reduces gas formation to a minimum.

The rigid exclusion of foods which I particularly like but which I know by experience will upset me has shown me the full significance of the story of Adam and Eve and the Forbidden Fruit. For three years I have eaten neither fresh fruit nor green vegetable, except when my will-power has broken down, and then I have invariably *paid the penalty*. I *do*, of course, reinforce this rigid diet with ample vitamin and mineral supplements. Food now holds little pleasure for me, and I eat only the minimum necessary to keep my weight at 9 st. 6 lb. —rather low for my age and height. Several times I have noted signs of a mild vitamin deficiency, such as sore tongue, angular stomatitis, and on *one occasion* skin petechiæ, which have disappeared with ample amounts of the required vitamin. I am firmly convinced that this peculiar diet has been *the most* important single factor in my improvement.

I can walk as quickly as most of my colleagues without any shortness of breath. But vigorous exercise soon fatigues me and I never participate in it. I was very fond of all sports, and as a schoolboy was as proficient at games as any of my school-friends, but now I take my recreation as a spectator only. When people accuse me of laziness for this, I take it as a compliment that my disability is so well concealed.

When I get a severe attack of colic—and I have had only one in the past year—I always adopt the same treatment: bed; a hot-water bottle applied to the most painful part; and a dose of an antispasmodic such as 'Trasentin' or pethidine, repeated 3-hourly if required. Food, apart from fluids, is excluded until the attack is over. With the cessation of the pain appetite soon returns, but for two or three days I am more than usually cautious and continue to take only fluids and semi-solids.

As is common in Crohn's disease, I normally have diarrhœa, with 4–6 loose stools daily. This is, paradoxically, of great importance to me, for if the bowels do not open for longer than 6 hours I get some abdominal discomfort. When I have taken remedies to stop the diarrhœa I have always regretted it. The abdominal discomfort increases as the stools became solid, and finally, if the bowels remain closed for 24 hours or so an attack of colic starts. Many years of diarrhœa have caused me no noticeable ill effects. I often feel thirsty and always try to compensate for the extra fluid lo lrinking as soon as I feel the slightest thirst. My y intake of fluid is at least five pints, of which virtually e is alcoholic. I also take extra salt by mouth in effort to avoid chloride depletion. My experience been, therefore, that while the diarrhœa is no doubt iological it constitutes an indispensable safety valve. motional upsets undoubtedly have an aggravating :t on my ailment. As a medical student, my symptoms were invariably worse before exams, and since I ified the ordeal of interviewing committees has had same effect. I always feel best when working hard, so have learnt to dislike holidays. Perhaps what me good is having my mind occupied with problems e interesting than my illness.

nere is nothing in my history which suggests a cause this disease. I was perfectly healthy from birth l early adolescence. It may be significant that until age I seemed likely to be tall, but from the time n my first symptoms appeared I stopped growing erhaps defective intestinal absorption explains this. re is no family history of tuberculosis, my chest ograph has always been normal, and tubercle bacilli e not been demonstrated by any routine test on ls, &c. The only environmental factor worth recording nat for several years in childhood I drank raw cows' . So the ætiological agent remains obscure, but one is clear—that the measures adopted have transned a serious disability into one of trivial dimensions.

Medicine and the Law

Claim of Official Privilege

HE inquest on Squadron Sergeant-Major J. E. Pettitt, d 37, who dropped dead during a drill course at the ırds' depot at Caterham, was resumed on Feb. 1. the previous hearing[1] the court had been adjourned order to obtain the evidence of the Army doctor who l examined the deceased before he left Germany for erham.

his witness said that he examined Pettitt on Dec. 30; titt told him that he had been playing rugby football ularly until two years ago and had been a champion ight-lifter. The examination showed Pettitt's bloodssure to be normal; there was no hardening of the eries and no clinical evidence of cardiac enlargement. ecropsy had shown that the heart weighed over 24 oz. more than twice the normal weight for a man with e physique of the deceased.) The witness agreed that e Army instructions for the Caterham course required personnel to bring a medical certificate stating that ey were fit to undergo it. His certificate had not ferred to fitness, only to freedom from infection; was the deceased's responsibility to see that he had certificate of fitness. Asked if he would have signed certificate of fitness, the witness replied in the negative; ettitt told him that for two years he had been doing fice work in connection with German civilian-labour nits. Pettitt had said he was going on a senior N.C.O.'s ourse; if the witness had known that it was a strenuous rill course, he would have advised a period of training y way of a "tune-up." The witness added that he imself had not seen Pettitt's medical-history sheet.

When the coroner called for this document, which had ot been produced at the previous hearing, counsel ho appeared on behalf of the War Office declined to nake it available; it was a document, he said, for which rivilege was always claimed on behalf of the Crown; e produced a certificate, signed by the Secretary of State for War, claiming privilege on the grounds of ublic interest. The coroner, recording a verdict that leath was due to natural causes, said he was obliged to accept the War Office's refusal, but it operated harshly against the family of the deceased, who had very good reasons for knowing his medical history. Since the last hearing, added the coroner, he had received many letters from relatives of other soldiers where access to medical records had been denied.

The medical profession knows best the type of privilege which, based on the confidential relationship between doctors and patients, is maintained in the interests of the patient to protect him from disclosure. The "public interest," on behalf of which the War Office has claimed privilege, might presumably be based on the requirements of national security, not here in issue. It could also be based on the responsibility to administer the military forces free from external supervision, or on the favoured position of the Crown as litigant when a subject attempts to bring a civil action in the law-courts. The Crown Proceedings Act of 1947 did much to assimilate the position of the Crown to that of an ordinary litigant. Section 10, to be sure, contained an important exception for the Armed Forces; the War Office was not going to risk exposure to an action for damages for negligence because "someone had blundered" in a future charge of the Light Brigade. Section 28, it is true, allowed the High Court and the county courts to order the Crown to make what lawyers call "discovery" of relevant documents and to produce them for inspection; but a significant proviso saved "any rule of law which authorises or requires the withholding of any document" on the ground that disclosure would be "injurious to the public interest." At Caterham the coroner described the position, not without reason, as "unsatisfactory." When Parliament reassembles, the Secretary of State for War may be invited to elucidate it at question time.

Public Health

Control of Narcotics

IN its latest report, the Permanent Central Opium Board[1] observes that, if the figures so far supplied are taken at their face value, the world licit production of opium in 1948 amounted to 739 tons. The world total for the manufacture of morphine in 1948 is given provisionally as 55·5 tons—equalling the highest on record. The quantities of morphine remaining available for use as such have dropped not only relatively but absolutely—from an average of 8·5 tons in each of the years 1934–37 to 5·5 tons in 1948. This downward trend is attributed both to increasing use of morphine derivatives and also to the introduction of synthetic narcotics.

In England Now

A Running Commentary by Peripatetic Correspondents

IT has happened—in America, of course. The proceedings at a medical meeting have been broadcast so that doctors can listen in their own homes and offices with the least expenditure of time and energy. Dr. Benjamin P. Watson, president of the New York Academy of Medicine, in inaugurating the Academy's transmissions of its scientific sessions over the local radio station, hoped that "hearing the voice of the lecturer and noting his emphasis on certain parts of his presentation may convey more clearly his thoughts and conclusions than would the reading of his words in cold print." Since all Americans are born broadcasters this may well be so. I feel that if many of us were to read our papers over the wireless they would be even more inaudible and incomprehensible than when we read them at meetings. But the audience could switch off, instead of having to move silently about on their seats, with "watching how the chairman takes it" as the only diversion. Clearly, until television can be allied to sound recordings of meetings—which is probably only a matter of time—lecturers will be deprived of some happy compensations they now enjoy. No longer can they say: "May I have the next slide please?—Oh, I'm sorry, I should have shown you this one before I went on to the present case." And, wedded to the microphone, they will not be able to wander about with the pointer. The old-time medical joke will go, too, but that has been doomed ever since women were admitted to all medical schools.

The New York Academy is asking practitioners when they would like the broadcasts and what they should be about. The first broadcast was a recording of a discussion on 'Cortisone' and A.C.T.H. Perhaps one day we shall be having similar broadcasts over here, for the B.B.C. is experimenting with frequency modulation, which is the system of very-short-wave local transmission used by Station WNYC in New York. It is true that lay people as well as doctors will be able to listen to the broadcasts; but this is no contra-indication, for they will not understand much and will probably give up listening after the novelty has worn off. My chief regret is that I shall no longer be able to indicate that the meeting has gone on long enough by walking stealthily out.

* * *

There is a peculiar malaise which follows the taking of sulphonamides, as we all know. Presumably this is a toxic effect, but what part of the brain mechanism is particularly affected by the circulating poison? For the feeling is real enough, as I can now testify. A friend of mine, who has a high administrative post and is a well-known writer as well, wrote to me of the dejection the drugs produced in him, leading to thoughts of suicide; and our vicar, a man of strong character and much learning, told me that he had had to beg his doctor to stop the tablets, for he could not bear the depression any longer. But it was the cat that moved me most. It is no use saying that depression comes because it is expected, or that only people with constitutional predisposition get it. "Depression" may not be the right word, but whatever it is my cat had it, and no-one had whispered into his black velvet ear that the tablets he was made to swallow would make him feel like death; nor is he temperamentally melancholic. The infection was checked, but each morning he crawled out of his basket to the sunniest spot on the lawn under a cypress hedge and lay as if waiting for death all day. He took food and drink when it was put under his nose, but he would not move towards it, and in the evening we had to pick up his limp body and carry him back to his basket. He made a good recovery in time, and today is the most vigorous and playful cat imaginable, but he was a sad sight then.

My own turn came lately, and I was quite placid about it, for I was to have the newest and least toxic of the drugs, and I have no tendency to extremes of mood—I expected, in fact, nothing but good. Yet, as the treatment continued, I began to feel curiously and horribly weak. On the last day I was told I could get up for tea, but after an hour, when I had enjoyed both Christmas cake and the radio—there was no mental depression in my case—I felt for bed as no doubt the cat did [illegible] the cypress hedge, and I crawled back. The fever had gone, my pulse was strong and normal, head clear and appetite returning, yet the life had gone out of me. It was as if the springs of action had run down. I l[illegible] inert, as the cat had done. When the time came in the evening for the last dose, something obscure but powerful in me rebelled; I meant to take it but couldn't. I don't suppose it mattered, but I feel guilty about it and shall sympathise in future (though secretly) with the patients who throw their tablets out of the window when [illegible] is looking.

* * *

The Membership is a very useful qualifying examination, and with it one can usually rely on getting a [illegible] junior house-job in one of the less frequented sidewalks of medicine, such as pseudosurgical psychiatry or dialectical venereology, if one has pull and an ingratiating smile. But my *chief tells me that one* must have something more imposing if one is to aspire to the higher planes of mid-stream medicine. I rather fancy a [illegible] myself—it sounds impressively austere, and with it [illegible] could always become a rural dean if the worst expectations of the N.H.S. became fact. What to choose for one's thesis, therein lies the problem; perhaps the *incidence of wing scapula among* the lesser British [illegible] would fill the bill?

* * *

My son's spelling is not his strong point, and I was relieved when he was accepted by my old school in Edinburgh. Three weeks ago he started his first term as a boarder, and his weekly letters are eagerly awaited by his mother. Being a fairly normal little boy he made the expected request for some addition to his diet, and in due course he was sent a parcel containing apples and a Swiss roll, among other items. The following letter has just been received.

"Dier Mum I hop you are verey well. that pasel [illegible] sent had a mous in it. he had eeten half the swis role [illegible] of the apels. luv from John.

I wonder. Did a mouse travel all the way to Edinburgh from Bristol in a parcel or are the Edinburgh mice very quick off the mark?

* * *

At a West of England agricultural show a while ago a Friesian cow was exhibited (and ignominiously placed second in its class) which had throughout the month of May produced, on average, 20 gallons of milk a day—enough to fill 160 pint milk bottles. More recently the New Zealand press informed us of a cow from Hamilton, New Zealand, which, in its 15 years of life, had given 122,000 lb. of milk, equalling 150 times its own weight.

How far is this selective interference with an old friend to be allowed to go? Already the victims walk with *difficulty; the veins coursing along* their bellies are big enough for venipuncture to be performed on them with a cannulated crowbar; and decompression, in the form of milking, must be done every six hours to prevent them bursting.

On, on till all non-essentials have been outbred and the goal is finally gained—an oval protoplasmic mass lying in a white-tiled byre, sans eyes, sans ears, sans horns, sans teeth, sans legs, sans everything but at one end a stoma, into which is shovelled at appropriate intervals a standard quantity of predigested, hydr[illegible] fortified, vitaminised, non-residue extract of grass, and amidships an imperceptible transformation into udder ending posteriorly in teats, arrayed like organ-stops, cascading milk into the moving churns beneath; the whole observed disinterestedly by an official, a representative, two spokesmen, and a delegate.

And the tail—hardly a non-essential? Then stick it on top, to wave like the tentacles of the delicate sea anemone, dispelling the hungry hornet and bidding a sad farewell to the gentle cow we used to know. Good cause had she to ruminate.

Letters to the Editor

THE CHEST PHYSICIAN

:,—*The disastrous plight of the tuberculous* has been y quoted in your journal, in the *Times*, and in other and weekly papers.

ring the past week we have openly heard of the d positive action taken by the Ministry of Health, July 5, 1948, in the realm of tuberculosis. Firstly, . arrived with a flourish of trumpets, but presently hed in the mysterious darkness of a night. Now ear that consultant chest physicians are to have a on of their salary paid at a rate considerably lower that offered to consultant medical staff. This on is in respect of the preventive and aftercare ts of the work undertaken by these physicians.

e we really living in the era of preventive medicine? the Ministry, whose very existence is based on entive medicine, really consider that prevention e divorced from clinical medicine, and that it should inked as of lesser import? This action has been 1 at the behest of local authorities, who have powers, r section 28 of the National Health Service Act, to ide aftercare. Considerable lip-service is paid to after- at every tuberculosis conference, but in how many s are there adequate facilities? Not *one* local ority in Britain is administering its proper quota of c almoners, night sanatoria, sheltered workshops, rehabilitation centres. Yet these are the authorities hom the Ministry has yielded!

ave been urged to ventilate this matter for two main ons. It is agreed that in the past the average quality est-clinic staff was poor. Little consideration has given to the circumstances. A tuberculosis officer d obtain adequate promotion almost solely by seeking ation to the post of medical officer of health. The lts are evident throughout the land today. They not inspiring. For this reason few men of ability sidered this service as a career. In the N.H.S. a portion of chest-clinic physicians have been freely pted by their colleagues as consultants, and vacancies his grade have been widely advertised.

umbers of those in senior posts will be retiring in 15 years. It is absolutely essential that the chest- ic service should attract young postgraduates with d experience and ability. This is now occurring, and ruitment has been revolutionised. Regional boards e the opportunity of building an efficient organisation grapple with the present serious problem.

he editor of the *Economist* made some apt comments a recent broadcast[1]:

> " . . . if we are to succeed in restoring our efficiency, we re going to have to do some very difficult and unpleasant hings. We are going to have to show in ourselves a willing- ess to change, which is something that no human being ikes to do. We shall have to allow the more efficient method of doing things to supersede the less efficient, and the more efficient man to supersede the less efficient man. In fact the resuscitation of efficiency involves two of the things that human beings find hardest in the world to achieve, that is constant mental effort, and a continuous disturbance of settled habits. I do not believe that you can get that sort of thing by exhortation alone. You have got to make it worth people's while."

If the recent edict on salaries is allowed to remain, l chance of improving the service will immediately fade potential applicants turn to less exacting, but more munerative, posts. The real loser will be not the resent chest-clinic physician but the community.

Secondly, these instructions from the Ministry will ead to the involuntary, but compulsory, cancellation y regional hospital boards of some existing contracts. Legal advice has been sought and an opinion has been expressed *that the contracts issued to the profession have no legal validity.* I suggest that all members of the profession take notice of the manner in which they can be treated.

The proposals relating to chest-clinic physicians were formulated in secret, and none were allowed to express an opinion. In disputes affecting industry the workers are at least permitted to state their case.

Willesden Chest Clinic,
London, N.W.10.

C. H. C. TOUSSAINT.

INFLUENZAL MENINGITIS

SIR,—Dr. Ounsted's preliminary communication on *Hæmophilus influenzæ* meningitis in your issue of Jan. 28 reminded me of a very similar problem which arose early in the 1914–18 war when I was working with the late Dr. Creswell Shearer. There occurred an epidemic of meningococcal meningitis; and we eventually concluded that phagocytosis was the deciding factor and that this depended on the site from which the meningococcus was isolated. The following is the summary from our paper on the subject[1]:

> "As the result of the foregoing experiments we think we have obtained good evidence for thinking that under certain conditions the meningococcus can be taken up by the leucocytes but not killed by them. In the case of freshly isolated strains we have seen that the leucocytes will not take them up at first. With old laboratory cultures, on the other hand, ingestion on the part of the phagocytes takes place with great rapidity. In a short time the germs are killed and completely digested by the leucocytes. This happens also with the majority of the nasal strains we have examined from chronic 'carriers' although they show great individual differences.
>
> "In the intermediate stage between the fresh spinal condition and the naso-pharyngeal state, it can be shown experimentally that they are taken up, but not killed, by the leucocytes. They can be recovered from them after a period of 24 or 48, or even 60 hours, and grown on artificial media. If we can believe they behave similarly within the body, then we can understand how they might be carried into the spinal canal and there set up infection.
>
> "It might also explain why direct infection (apart from the 'carriers') seldom, if ever, takes place in cerebro-spinal fever; that is from patient to patient, attendant, or physician, etc., the phagocytes refusing to take up the germs in their virulent condition. In the 'carrier,' on the other hand, in the majority of instances, the germs have lost their virulence so completely that they are taken up and immediately killed and digested.
>
> "In conclusion: if the method of infection is by leucocytic conveyance, then the reason why direct infection is so uncommon is clear. The virulent organism is unsusceptible of being attacked by the phagocytes. The longer the germs grow in the 'carrier' throat, the more easily will they be ingested until a time is reached when, on ingestion, they are also destroyed. Somewhere between these two extremes, infection may produce the disease. The organism is sufficiently weakened to give in to the leucocytic attack, but not to lose its life in the battle. Should infection occur at this point, the leucocytes will pick them up from the mucous membrane of the naso-pharynx, and in the course of their wanderings will sometimes carry them into the spinal canal. There the liberated organisms will set up the disease, at the same time re-acquiring the power of resisting the attacks of the leucocytes in the presence of normal serum."

We also thought that our hypothesis was supported by the appearance of the phagocytes in the cerebrospinal fluid. These were often seen to be bursting with meningococci, which must have multiplied in the bodies of the leucocytes. The answer in influenzal meningitis, then, may well be the same as in meningococcal meningitis with the addition of the variation in immunity at the different ages.

The sibling pattern described by Dr. Ounsted would fit in with the closer contact between the children in a family of more than one or two, together with the low bactericidal power of the blood at the susceptible age.

---

[1] *Proc. roy. Soc.* B. 1917, 89, 422.

On this hypothesis we need not make the unlikely assumption of the evolution by "passage" of a special strain of the *H. influenzæ* organism which could pass the meningeal barrier.

London, W.1. H. WARREN CROWE.

CURARE AND THE PREGNANT UTERUS

SIR,—In view of recent correspondence,[1] [2] we feel that it might be of interest to mention preliminary findings of the action of *d*-tubocurarine (10–15 mg.) on the human uterus early in pregnancy.

Using internal balloons, records of uterine movements were made in six pregnancies which ranged from 52 days to 22 weeks. All cases but one were under cyclopropane anæsthesia.

The outstanding feature was that in no case did *d*-tubocurarine produce marked increase in tone or contractions of the uterus. The results were variable, some cases showing increase and some decrease of tone and contractions. All changes were slight and negligible when compared with those produced by oxytocin or vasopressin.

Whilst we realise that these findings may not necessarily apply to the uterus at term, they do not support the contention that the great increase in uterine tone in Dr. Rollason's case [1] was due to *d*-tubocurarine.

PROLAPSED INTERVERTEBRAL DISC

SIR,—The article published on Jan. 28 in your Disabilities series, puts surgery in a rather unfavourable light and therefore invites comment.

Surgery in this case appears on the same empirical level as any manipulative or osteopathic procedure, and many patients with two years of postoperative relief from sciatica may be wondering what their chance of relapse may be. It would seem to me that your contributor has been deprived of the benefits of surgery through three, or even four, errors of surgical judgment.

The first error was to explore the lumbar discs in the hope of finding a protrusion in a case of lumbago. It is still only presumptive that disc protrusion is the cause of lumbago. It is probable, though not proved, that lumbago is caused by the stretching of the annulus fibrosus before a discrete protrusion has formed, though it is open to question whether curettage of the disc is the correct treatment at this stage; the experience in this case suggests that it is not. In lumbago the side of the protrusion has not yet declared itself, as it does in sciatica, and the surgeon has thus very little preoperative information when embarking on exploration.

The second error was to omit to perform the correct orthopædic operation for chronic lumbago. If lumbago in an active young person is chronic enough, and the attacks are severe enough, to warrant surgery (as it undoubtedly seemed to be in this case) the soundest operation is that of lumbosacral fusion performed without exploration of the spinal canal. Though ordinary lumbago is exceedingly common, the cases which qualify for this operation are rare. The results of lumbosacral fusion are gratifying and permanent.

The third error—understandable in the circumstances—was not to operate when the disc protrusion declared itself by producing sciatica. There can be no doubt that this patient still has a large protrusion and may still have further attacks of sciatica, and that his six months of conservative treatment may still be futile.

The possibility of a fourth error is only a guess. At the operation for lumbago the disc may have been wrongly identified. This is not a beginner's mistake as I found out on my (approximately) ninetieth and my hundredth cases. It seems possible, through local anatomical variations, to mistake the lamina of the 5th lumbar vertebra for the upper limit of the sacrum, even though a large area of the sacrum has been exposed, unless the surgeon is aware of this obvious source of error. This means that what is taken to be the lowest lumbar disc is in reality only the 4th disc. For this reason I feel that the spinous processes should be identified by some radiological technique before or during operation, even by the most skilled operator.

In disc sciatica causing the amount of disability which your contributor describes, the operative removal of a disc protrusion is one of the most gratifying procedures in surgery and is fit to hold a place among any of the greatest achievements of modern science; it is important to reaffirm this opinion when experiences are recounted which appear to cloud the issue.

Manchester Royal Infirmary. JOHN CHARNLEY

THE EPILEPTIC'S DIFFICULTIES

SIR,—*Others find it hard to understand* the epileptic's difficulties. As a sufferer from grand mal I have found that broadly these are threefold.

First, nobody is entirely "master of his fate," but the normally healthy person can both think and behave as if he were. For the epileptic this is impossible. The feeling that at any moment, with no chance of escape, he can have his life blacked out, his whole pattern of living interrupted, can be at times—and particularly just after an attack—quite terrifying. Even if he can overcome this feeling he has to behave as though nothing which he does or plans is certain. It is so easy to come to regard life as a mere matter of existing, and little more.

Secondly, there is the feeling of resentment. I say *that this is a feature of most long-term* afflictions, yet I believe that it must affect epileptics more than most. Just because, between attacks, there is no outward sign, just because one's disability is what one might call an "invisible wooden leg," it is almost impossible to get other people to accept one's limitations at their true value. It is bad enough to think of all the things that might have been but cannot be, in the matter of [illegible] and other activities, without feeling that one must [illegible] still more because an employer, or one's own sense of fairness, decides to play safe.

Thirdly, there is the attitude of others to epilepsy as a disease. It is not so much the fact that by its nature it discourages sympathy except in those who come in close contact with it. It is the quite positive attitude among those who are ill-informed—and how many they are—that epilepsy is a "little bit queer" and faintly repulsive.

These are the difficulties. How can they be countered? I think that within his limitations the epileptic must try to live a life sufficiently active, and *varied*, to be able *to tell himself: "Even if I were not epileptic* I could *not make my life any fuller than it is;* if there are things I cannot do, I could not in any case do them except by forgoing something which I now do; besides which I can already do some things which other people, better off than I am, cannot do." That sounds pompous, but I can say from experience that it does work, and the ability to out-do normal people in normal activities becomes a matter of pride.

Secondly, it is a great help if one *knows* what to expect. Knowing such things as the danger-times of the day, how often the *attacks are likely to come*, and so on, helps to bring the problem down to its proper proportions. This probably sounds obvious, yet it was several years before I really knew what I was up against. I feel that a comprehensive, matter-of-fact description by the doctor could do a lot.

Thirdly, once the *epileptic* knows what he can expect, relations and friends should be very wary of offering unsought protection. If he is to live at all fully, he is bound to expose himself to risks which would not normally ified. He is probably far more aware of these ıan his "protectors" seem to think, and is almost ly taking them quite deliberately in his attempt a normal life. He is not likely to forget his ities, but he should never be chained to them.

ANON.

INCESS TSAHAI MEMORIAL HOSPITAL

—I shall be grateful if you will allow me to appeal ıations to buy the surgical instruments required nplete the equipment of the main operating- of the Princess Tsahai Memorial Hospital in Ababa. The sum required for this purpose is it would carry the hospital a substantial stage d towards the opening, which it is now hoped will lace at an early date.

Neville Goodman,[1] late director of field services of orld Health Organisation, has testified to the need of the hospital for the treatment of patients, articularly as a training-centre for nurses. The atic training of fully qualified hospital nurses has be initiated in Ethiopia. By praiseworthy efforts the years which have elapsed since the country berated with British aid in 1941, the Ethiopian ion department has prepared a number of young for hospital training. Funds for this are in sight, he hospital is open.

ques, and postal orders should be drawn in favour Princess Tsahai Memorial Hospital, and addressed hon. treasurers (Lord Horder and Lord Amulree), essrs. Gould and Prideaux, the hon. chartered ıtants, 88, Bishopsgate, London, E.C.2.

WINSTER
Chairman.

EATMENT OF RHEUMATOID ARTHRITIS

,—Dr. Landsberg's letter of Jan. 21 on the treatment eumatoid arthritis with various steroid hormones scorbic acid prompts me to describe two cases of ıatoid arthritis treated in Johannesburg in 1948 methyl testosterone, administered orally.

h patients were European males with a long history ıd 5 years respectively) of generalised joint-pains and nities, worse in the smaller joints, and associated with tion in the range of movements, ulnar deviation of the , and pronounced increase of the erythrocyte-sedimenta- ate. In each case the facies and unusually large hands eet suggested acromegaly, this being supported by radio- ıl evidence of thickening of the skull bones, widening e jaw-angle, enlargement of frontal sinuses, lateral and oposterior enlargement of vertebral bodies[2] tufting of nal phalanges, and broadening of the anterior ends of ibs. The pituitary fossa was normal in size, but there an obvious "bec acromegalique"[3] in one case. Both nts had an impaired glucose-tolerance and glycosuria, raised blood uric-acid content with a normal blood-urea.

ıe possibility of an eosinophil adenoma of the anterior itary was considered, since joint-pains and "arth- " are not infrequent in acromegaly.[4] In an attempt epress anterior-pituitary activity, methyl testosterone given by mouth, 30 mg. thrice daily for a week, ıout keeping the patients in hospital.

ı the first case there was remarkable relief from t-pains and an obvious increase in the mobility of joints within four days of the first dose. Dosage reduced to 10 mg. twice daily for three weeks, and ı to 10 mg. on alternate days for a month. During time pain was absent and the striking improvement he patient's clinical condition was maintained, while his weight increased from 130 to 150 lb. (ten years previously it had been 230 lb.). The second patient had a severe exacerbation of the symptoms (headaches and joint-pains) during a week's treatment, but after this was stopped he was so much improved subjectively that he asked for more tablets.

Follow-up was prevented by my departure from South Africa, but the promising initial response justifies a more comprehensive investigation of methyl testosterone in rheumatoid arthritis, with or without associated acromegaly. No clear indication arose as to which type of case might react favourably and which might, at least initially, be aggravated; but it may be significant that the former result occurred in a severely emaciated patient, and the latter in one who had lost little weight. This accords well with the claim of Fox[5] that only emaciated patients with rheumatoid arthritis respond favourably to the combined treatment with deoxycortone acetate and ascorbic acid, while the symptoms are often worsened in those who have had no loss of weight.

University of Oxford.

D. H. P. STREETEN.

POSTOPERATIVE PARALYSIS IN THE UPPER EXTREMITY

SIR,—May I congratulate Mr. Ewing and Dr. Kiloh on their excellent articles of Jan. 21 on brachial-plexus lesions following operation.

Mr. Ewing lays great emphasis on the use of curare and the placing of the patient in the Trendelenburg position as causes of the brachial palsy, but I do not agree with him entirely on this. Some years ago, before curare was introduced, I had a case which developed a postoperative brachial-nerve palsy, and at the time I was at a loss to know why this had developed.

The lesion occurred in a man who had undergone cholecystectomy. He was not placed in the Trendelenburg position, but his arms were kept hyperabducted and hyperextended and everted throughout the operation. This position was maintained by keeping both wrists tied to the top of the table by means of a cuff bandage and cotton-wool. After the operation the patient developed a brachial palsy on the right side. With the aid of physiotherapy, the arm recovered full function within a few months, but nevertheless the patient (whom I saw on many subsequent occasions) continued to complain bitterly of aching pain in the right upper limb and was unable to resume work for a considerable time after his operation.

I notice that Dr. Kiloh mentions post-fixation of the brachial plexus as a possible predisposing cause of plexus lesions. I consider this the prime factor, for the following reason. When the plexus is post-fixed (arising from the 6th, 7th, and 8th cervical and the 1st and 2nd thoracic segments instead of the 5th, 6th, 7th, and 8th cervical and the 1st thoracic segments) it certainly has a longer course to run and can be more easily stretched when the limb is in a position of abduction and eversion. I do not know what is the percentage of people who have a post-fixation plexus. Despite the large number of patients who are operated on in the Trendelenburg position and who have curare as an adjunct to their anæsthesia, the development of the brachial-palsy syndrome is rare. Is it not possible to assume that it occurs only in those patients who have a post-fixation brachial plexus and who have their arms kept in abduction during an operation (not necessarily in the Trendelenburg position)?

Having seen one case develop, I no longer have my patients' arms hyperabducted and tied to the top of the table. In my opinion, the ideal position is that in which the arms are crossed over the chest and tucked away under the patient's shirt or nightgown. If the arm has to be abducted for the anæsthetic, it is advisable to see

that the abduction be less than 90°, and in addition the forearm should be kept pronated. This is an ideal position, for then the intravenous administration can be given into a vein which runs just above the lower end of the radius on its dorsal aspect; this vein is constant in this position. I am not in favour of administering intravenous fluids into the leg. There is not only a risk of thrombosis of the veins of the leg, but in my experience the incision in the ankle region easily becomes septic. Even when healed, the scar may remain tender for a long time, and I have seen patients who even after many years complain of this tenderness persisting. Recently a patient in my hospital developed lymphangitis following exposure of a vein in the ankle region for intravenous administration, there being no phlebitis present.

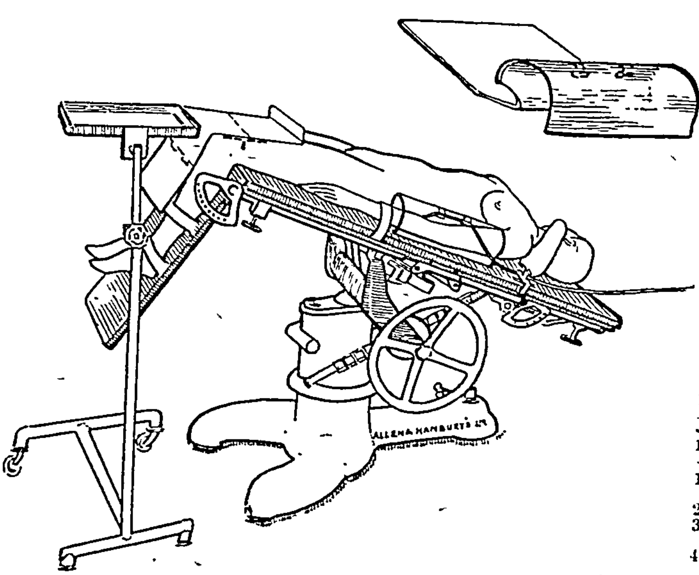
Lastly, I should like to mention one more position which I consider to be pernicious—namely, that in which the patient is made to sit with the hands under the buttocks. In this position the weight of the patient on his hands interferes with the blood-supply to the digits, as is evident from the blanching which can be observed after operation. I have heard from a reliable source of one such case in which gangrene of a digit developed.

London, W.1. MAURICE LEE.

SIR,—Mr. Ewing's article of Jan. 21 leads us to describe a simple but effective arm-splint, designed because of two cases of brachial-plexus injury following gynæcological operation. Both cases occurred after having the arm abducted during operation with the table in fairly steep Trendelenburg position. In one case the abduction was for the purpose of blood-pressure recordings, in the other for a drip transfusion. The anæsthesia was different in each case; the first received thiopentone, *d*-tubocurarine chloride, and cyclopropane, and the second a spinal anæsthetic, using light 'Nupercaine,' intermittent doses of thiopentone, and nitrous oxide and oxygen.

The splint, illustrated here, was designed to be used during the operation. It was constructed by Mr. E. Simmons, senior technician of the department of obstetrics and gynæcology. It consists of a sheet of 'Perspex' glass, one-third of which is curved to form a tunnel. The ends of the inner wall of the tunnel are cut away to avoid pressure on the upper arm. Accordingly the splint can be used for either arm.

To place the splint in position, the patient is lifted bodily off the table and the flat portion is adjusted beneath her, the arm being eased into the tunnel to be alongside the body. Needless to say, the intravenous needle is in position before this manœuvre is carried Care is taken to avoid any pressure-points, and the is controlled by a towel passing under the patient. T important points must be borne in mind:



1. The needle must be fixed into a satisfactory ve firmly held in place with strapping.
2. The splint must be arranged in position before the of the operation.
3. An extension to the rubber tubing of the intra giving-set is necessary. We have extra lengths of pres tubing, about 20 in. long, fitted with suitable adapt sterilised in readiness. Pressure-tubing is essential to a kinking.

We have found this device very satisfactory i continuous intravenous therapy has been m throughout the operation.

MYSTERIOUS MARRIAGE

SIR,—The last paragraph of Dr. Howe's l Jan. 28 calls for some comment.

One of the outstanding characteristics of the o sional neurotic is the inner-compulsion for exa and precision, quite regardless of its external ne but before arriving at such a diagnosis the "observer" must be aware of the real problem which confronts "observed," the rationale in dealing with it, and issues at-stake. Otherwise he may form an er opinion that the "observed" is making a lot of about nothing. To put anything right, the more w learn about its function and the way it works, the likely are we to be successful; so in analysis the m know of mental mechanisms, the more cert therapy to succeed. The study of psychop largely involves Dr. Howe's imponderables, but h we to perfect our technique if we follow his sugges of keeping our fairies at the bottom of the garden!

Analysis is no more detrimental to the enjoyment art and things of the imagination than, say, a tec knowledge of how films are produced is to the enjoy of a good film seen at the cinema.

Bishops Stortford, Herts. D. N. HARDCASTLE

TETRAETHYLAMMONIUM BROMIDE IN RHEUMATOID ARTHRITIS

SIR,—If Dr. Howell's conception (Feb. 4, p. 20 the mechanism by which tetraethylammonium bro relieves pain in an acute exacerbation of rheum arthritis is the correct one, there is a marked discrep- with the results of cervicothoracic sympathectomy.

It was precisely in that type of case where Dr. H failed to relieve pain that Rowntree and Adson[1] Adson [2] claimed success by cervicothoracic sy thectomy. I refer to the patient with a periart type of arthritis with comparatively little joint in ment. I think I am right in stating that no cla ever been made that the pain endured by a patient the joint surfaces predominantly involved is alle by sympathectomy. On the contrary, White and S wick [3] consider that it is logical to recommend pathectomy "only if superimposed vasomo sudomotor disturbances are a cause of serious dis

I should be interested to know the grounds for the ment which Dr. Howell quotes: "the nerve supply of joints and ligaments is derived from the symp nervous system."[4] This repudiation of the view expr

DIPHTHERIA IMMUNISATION

—I would like to congratulate Miss Barr, Mr.
y, and Dr. Randall on their excellent piece of
ch published in your issue of Jan. 7. I do rather
exception, however, to the assertion contained in
t the Schick test should never be used in funda-
l work designed to throw light on methods of
nisation, &c.

uite agree that, in such an investigation as they have
described, blood-antitoxin titrations are essential
fundamental facts are to be understood. Yet,
accepts the production of the Schick-negative state,
al months after inoculation, as the criterion of a
actory basal immunity (as I am bound to conclude
many years' work, that it nearly always is), there
nany lines of investigation which can profitably
ursued, using the Schick test as the yard-measure.
ık my belief is justified by an experience over many
, of Schick-negative subjects, in enormous numbers,
have been exposed to infection, with only one (?)
due to diphtheria during that time. I, personally,
learnt an immense amount with the aid of the
and many people have acted on my findings. I
, and believe, that I have led no-one astray.

ay I mischievously remind these writers why
come diphtheria P.T.A.P., contains 10 mg. of alumi-
phosphate per ml.? This optimum figure was
rmined by me for Holt, when he was perfecting his
inal P.T.A.P., solely by intelligent use of the Schick
I do not fear any challenge to this deduction,
pt that larger amounts of aluminium phosphate
to 15 mg. per ml.) have a slight advantage when
intended to undertake single-injection prophylaxis.

do not propose to set forth in detail other numerous
inal observations in which the Schick test has been
ally, and can only say that I feel sure that your
tributors (and my old friends at Beckenham) did not
lly mean to be quite so sweeping in their assertions.

GUY BOUSFIELD.

ROMBOANGIITIS OBLITERANS TREATED BY HYPOGLYCÆMIA

SIR,—I have just learned that the treatment of
omboangiitis obliterans with large doses of insulin
ich I discussed in an article last November[1] is being
d as a routine procedure at Wroclaw, Poland.

This method of treatment was introduced in 1946 at
School of Medicine Hospital of Wroclaw University,
Dr. J. Kaniak. Since it has proved successful, patients
ffering from thromboangiitis obliterans have been
ferred from all over the country to Wroclaw, where a
ntre for treatment of vascular diseases has been
ened. So far about 200 cases have been treated
ccessfully by insulin injections.

Dr. Kaniak has published an article on the subject[2]; and I understand that shortly he is going to publish his observations on the modus operandi. His findings from a large number of cases show that in advanced cases of thromboangiitis obliterans treatment by hypoglycæmia is of value.

Penley Hall Hospital, near Wrexham,
Denbighshire.

H. MAZANEK.

INSULIN AND JAUNDICE

SIR,—The use of insulin in jaundice, and particularly in infective hepatitis, does not appear to be well known. I have long had the impression that this treatment is very helpful. The effect seems to be an increase in the glycogen content of the liver, thus increasing its function and resistance.

The insulin is always given with glucose: about 20 units of insulin to 30 g. of glucose per day is what I have always used, but there has been some difference of opinion about dosage, and Henschen suggests 1 unit of insulin to 2 g. of sugar. In cases of cirrhosis, syphilis, or carcinoma, less sugar is required; with greatly impaired liver function there is danger of hyperglycæmic coma.

Patients treated with insulin and glucose nearly always feel better; their appetities improve, and their tongues become more moist and clean. The period of convalescence is greatly shortened. There have been several accounts of this treatment.[3]

London, S.W.4.

J. E. O'LOGHLEN.

PNEUMOCONIOSIS AFTER EXPOSURE TO SULPHUR DIOXIDE FUMES AND DUST FROM COKE FIRES

SIR,—Dr. Fisher (Jan. 14) rightly defines the implications of our paper, provided that the conclusions therein are valid. Purposely, we stated that they were tentative. It was our aim to draw attention to the occurrence—not to speculate on the possible incidence—of pneumoconiosis in boiler-stokers and others. Dr. Fisher over-estimates its potential frequency. In an industrial city of 300,000 population we encountered, on average, 1 case each year over nine years. In the country as a whole (population 50,000,000), if it were industrialised equally to Hull—which it is not—one might expect, on such a basis, the discovery of 170 cases each year.

His objection that the "ten cases are hardly evidence" we accept, not because of the small number but, as was made clear in the discussion, because post-mortem proof has not yet been obtained. Tuberculosis was excluded on the grounds stated, by the subsequent course of the illness in those who are still under observation, and because none of the workers has been later notified as tuberculous. Moreover, the X-ray picture did not resemble that of fibroid tubercle. The sample of dust was a "pooled" sample collected by three stokers from hearth, bench, window-sill, &c., in the course of a day's work. Analysis was done of that fraction of dust measuring about 2 μ—i.e., of most active and pathogenic size. (The statement in our paper that the sample was obtained by one stoker is wrong—a fact only discovered later.)

We did not consider it necessary, nor did we have the opportunity, to inspect the working conditions of all the men. Of those we saw, some were good, others bad. In a large gas-works no risk of inhaling dust or sulphur dioxide seemed to us to be present. There we also visited the blacksmith's shop, where dust was present but was not conspicuous in the air. The work environment of three boiler-stokers was far from good. Poor conditions were alleged to exist in a small gas-works which was not open to inspection by us.

---

[1] *Lancet*, 1949, ii, 935.

[2] *Przegl. lek.* 1948, 4. 272.

[3] Lepehne, G. *Munch. med. Wschr.* 1928, 75, 1171. Hegler, C. *Dtsch. med. Wschr.* 1934, 60, 475. Krauss, F. *Ibid*, 1936, 62, 1335.

The experience of Dr. Fisher in the medical supervision of those in a large number of works (presumably gas-works) has been that cases similar to ours have not been brought to light. He does not state whether chest radiography was used, without which the detection of chest disease and the elucidation of its cause are, in our submission, uncertain.

Since our paper was published, Dr. A. G. Heppleston has kindly brought to our notice his paper on the pathology of pneumoconiosis in Welsh coal-workers.[1] He found comparable changes—focal dust-lesions and focal emphysema—in the lungs of certain coke-workers. In a recent personal communication he states that these workers came from the local gas-works. They had died from conditions other than pneumoconiosis.

We believe that much industrial chest disease remains undiscovered. Trades in which there is already proof of the occurrence of disease among workers sufficient to cause partial or even total disablement have not been included, up to now, in the "schedule" of trades carrying rights of compensation. Routine chest radiography should be done in those working in bad conditions where there is dust, irrespective of its type. Even where work conditions are poor, most workers will doubtless be found to have healthy lungs.

That his workers are apparently immune does not entitle Dr. Fisher to infer that there is freedom from this type of chest disability wherever similar trades are conducted.

Tuberculosis Dispensary,
Hull.

LASAR DUNNER
R. HARDY
D. J. T. BAGNALL.

TITRE OF BLOOD-GROUP ANTIBODIES

SIR,—The activity of an antibody in vitro, which may or may not parallel its activity in vivo, is usually expressed as "titre."

The blood-grouping serologists reckon the titre of an antiserum as the highest dilution in saline which will still produce agglutination, not taking into account (as the bacteriologists do) the further dilution—usually another twice—in cell-suspending fluid when the agglutination reaction is set up. This is surely a convention which may mislead workers outside this special field, for it makes the titre appear lower than it actually is.

When doubling dilutions are used, the accuracy of the method depends largely upon the skill with which the antibody is diluted. An error in the first tube will be multiplied in each succeeding tube if this or any other geometrical method of dilution is used which involves a carry-over of ever-more-dilute serum from one tube to the next. An arithmetical method of dilution is not liable to so great an error. A good plan is to use a geometrical doubling dilution to obtain an approximate result, and if the titre is high to follow with an arithmetical method to get a more exact figure. It seems accurate enough to express the titre of a weak antibody as "between 1/2 and 1/4," but to say a strong one is "between 1/1024 and 1/2048" leaves a big gap to be covered. Such an antibody could next be tested at 1/1100, 1/1200, 1/1300, and so on up to 1/2000, in order to get a more exact end-point. Unless some such system is used the titres of strong antibodies are difficult to compare, for if we assume that a weak serum of titre 1/4 contains x units of antibody per unit volume (p.u.v.), a gain of another x units will produce a "one-tube rise" in titre to 1/8, whereas with a strong antibody of titre, say, 1/1024, containing 256 x units p.u.v., a gain of x, or 10 x, or even 100 x will not produce the "one-tube rise," which demands 256 x before the titre, as conventionally expressed in geometrical increments, any increase.

Again, the practice of calling the titre "1/1024" "1/8192" is surely absurd. While the accuracy of method may allow one to say "1/2" or "1 diluting technique is not accurate to one part in a thousand, which this convention implies is so. It seem less pretentious to call the dilutions 2^{-1}, 2^{-2}, and so forth.

National Blood Transfusion Association,
52, Lower Leeson Street, Dublin.

EARLE HACKETT

D.P.H. LONDON 1929-39

SIR,—We are most anxious to get into touch all old students of the London School of Hygiene Tropical Medicine who attended the D.P.H. classes between 1929 and 1939. We have already sent a letter to those whose addresses we could find, but there are many we have been unable to trace. We should be most grateful if all old students, whether they are at home or abroad, who took the D.P.H. courses between 1929 and 1939 and who have not yet received our letter would write to Dr. Windle Taylor, 51, Woodside Avenue, London, N.10, giving their addresses.

ACUTE DIVERTICULITIS OF THE CÆCUM AND ASCENDING COLON

SIR,—I read the article by Mr. Shaw and Dr. (Jan. 21) and the letter by Dr. Tasker (Jan. great interest and some sorrow: with interest because two very typical and well-known features were described; with sorrow, because neither Mr. Shaw Dr. Tasker conveyed the impression that he was with the fundamental work done on this condition his old school, Leeds.

W. H. Maxwell Telling embodied the results of own extensive investigations and those of numerous colleagues—notably Berkeley Moynihan, Gruner, [illegible]wood, and M. J. Stewart—from the Leeds General Infirmary, and reviewed the world literature in a series of papers of which the first, in 1908,[1] and the last, 1917,[2] were the most important; these are still classics in British medical literature.

While it is true that in recent years more instances of inflammation of solitary diverticula of the cæcum ascending colon have been found and reported abdominal surgeons, their occurrence has always well recognised and yet these cases remain uncommon numerically when contrasted with sigmoid diverticulitis. In 324 case-records Telling found that 6·25% of patients with diverticulitis presented with right-sided symptoms and he emphasised that when acute these symptoms practically indistinguishable from those of appendicitis. Telling and Gruner also dwelt at length on the mimicry by diverticulitis not only of carcinoma but also of hyperplastic tuberculosis. Dr. Tasker's case-report justifies their comment on the frequency with which extensive resections had been done under the mistaken impression of malignancy.

As a physician, I do not presume to discuss the [illegible] surgical treatment, but I do feel that every physician and surgeon should be thoroughly conversant with the diverse features of this condition, and that before embarking on extensive resections surgeons should always be ready to review unexpected findings in the abdomen with diverticulitis in mind.

Leeds. O. H. J. MAXWELL TELLING.

HOSPITAL BEDS

–One of the greatest obstacles to the full imple- ion of the National Health Service Act is the e of hospital accommodation. It is, therefore, tive, in the absence of any immediate prospect ling new hospitals, or extending the present ones, e best use should be made of the existing beds.

leading article last week lays stress on the percentage bed occupancy, which was 83% ig London hospitals in the early 1930s. Although ld aim at the highest figure possible, clearly the ls with a reputed 100% occupancy are con- adding a large number of extra beds for emer- ases. In practice there are many contingencies nevitably lower the percentage occupied during The number of patients during the Christmas s is often reduced by a third. The average er is also very loth to be admitted off the waiting- before Easter, Whitsun, or the August holidays. r wards have to be closed from time to time for ation and cleaning. You urge that the Minister investigate this matter. I am sure that there are uitful lines of inquiry which could reduce "bed e" in these days of "bed famine."

average stay of patients in similar hospitals greatly. It is well known that this figure is at its in the teaching hospitals with their adequate staff cilities. Many of the smaller hospitals, or those d some distance away from the big centres, depend equent consultant visits. Junior hospital staff tend y a "*clinical decision*" *until the patient has been* the responsible physician or surgeon. The loss, in of patient-days, by inadequate consultant staffing, very substantial.

ital beds are still used extensively for patients ng investigation. This is particularly true in ls where the outpatient department is not ade- y staffed or equipped. The cost to the State of gating a patient as an outpatient is much less than providing him with a hospital bed. An increase in stic facilities would release a large number of beds ly required for the patients needing treatment n only be provided in a hospital.

best and the maximum use should be made existing hospital beds. The disturbing factor of g shortage may prevent a substantial increase of modation even in the future.

iff. DAVID G. MORGAN.

THEMA EXUDATIVUM MULTIFORME AND EUMONIA TREATED WITH AUREOMYCIN

,—In view of Dr. Bettley's account (Jan. 14) of a of pemphigus benefited by 'Aureomycin,' and of t reports from the U.S.A. of its trial in some cases rmatitis herpetiformis and disseminated herpes ex, I would like to record the following case.

nan, aged 69, was admitted to St. Helier Hospital under re of Dr. Prosser Thomas on Oct. 4, 1949, suffering from ute bullous eruption with severe constitutional reaction. ad been taking phenobarbitone gr. $^1/_2$ twice daily on and nce June, 1948; and this was regarded as a possible

admission, his temperature was 101·4°F, pulse-rate r min., respirations 22 per min. The tongue was heavily and there was severe stomatitis with submucosal rrhage. The orbits were œdematous and discharging whole face was swollen and red and later exuded, leaving s round the eyes, mouth, and nose. The anogenital area similarly affected. On the limbs, and to a lesser extent trunk, were large patches of erythema or purpuric ery- a with thin blisters of varying size. The appearances typical of severe erythema bullosum or so-called ens-Johnson syndrome.

n examination a few crepitations were heard at the base ach lung. In the abdomen, the central nervous system, and the cardiovascular system, no abnormality was detected blood-pressure 120/80 mm. Hg. The blood-count was within normal limits, and blood-culture was negative; blood-urea 49 mg. per 100 ml. The urine contained a trace of protein with a moderate number of cellular, granular, and hyaline casts; culture contained *Bact. coli*. Radiography of chest showed an unfolded aorta.

The patient was treated at first with penicillin intramuscularly, 250,000 units four-hourly, 'Phenergan,' 25 mg. twice daily, and locally with saline compresses and calamine lotion or liniment with 0·5% crystal violet. His condition, however, rapidly deteriorated and by Oct. 7 was regarded as hopeless. He had become semicomatose and was very toxic and cyanosed. There were signs of consolidation at the base of the right lung and to a lesser extent at the left base; radiographs showed multiple small patches of bronchopneumonia throughout both lungs.

On the suggestion of Dr. C. P. Petch, the patient was given aureomycin in 1 g. doses every six hours for four days. The response was dramatic. In twelve hours the temperature became normal and it remained so. The patient soon became rational and the eruption rapidly regressed.

He made an uninterrupted recovery and was discharged to convalescence on Nov. 7, when radiography showed the lungs to be completely clear. He is now quite fit again and back at work.

St. Helier Hospital,
Carshalton, Surrey. W. E. CHURCH.

THE FIRST MEDICAL EXAMINATION

SIR,—Mr. Hentschel, in his letter of Jan. 28, says: "There is no doubt that the same standard is maintained for the external and internal examinations for London 1st M.B." It must, however, be extremely difficult to ensure a uniform standard even if, as he says, it is the practice for the same outside examiners to act in both examinations. I suggest that it would be fairer to all candidates if identical papers were set for the external and internal examinations, with a uniform system of marking: internal students at some colleges already take the same papers as external students, and there is no apparent reason why the remaining colleges should not fall into line. This suggestion also applies to the 2nd M.B., where again many medical schools have their own papers, so that the examination may well be easier at some schools than at others, and for internal students than for external (or vice versa). In the final M.B. examination there are common papers for all students.

London, W.2. F. WHITWAM JONES.

SIR,—In her letter of Jan. 21, Dr. Johnson expresses doubt whether the training, especially in schools, is really inadequate. May I be permitted to tell my experience of training from a student's viewpoint?

I was at school during the late war, and because of evacuation and other causes my education was badly interrupted. The final result was that although for higher school certificate I could study biology, there were no facilities or tutor for chemistry and, I think, also no teacher in physics. Hence, after National Service, when I found it difficult to gain entry to a medical school for 1st M.B., I decided to take intermediate B.SC. externally for an exemption.

In September, 1947, there were just over 20 students in my class taking the intermediate B.SC. course at a London technical college. The students' ages varied between 18 and 26 years. All studied physics, some 15 chemistry, but only 8 of us botany and zoology. The majority were aiming for an engineering qualification, and the rest for such varied ones as pharmaceutical (2), veterinary (1), pure chemistry (2), agricultural (1), and medical (2). The course lasted until July, 1948, when the examinations took place.

The students agreed that the lectures in physics were of good standard and adequate. However, the lecturer found himself obliged to use the calculus notation quite frequently, and this proved a handicap to the biologists. In chemistry the teacher was proficient in his subject but designed his lectures to cover only the main parts of the syllabus. For both zoology and botany, however, there was only one tutor and he was incompetent. Nine-tenths of his lectures were copied word for word from our own textbooks (which he borrowed) and then were read lifelessly to us. Frequently he misled us, and when corrected would admit his mistakes with deep regret. The Principal regretted that he was powerless to remedy the situation owing to the acute shortage of biology teachers. We were told that the previous year the biology students had studied without a teacher; but they had all failed, including a brilliant student working for medicine. He is now lost to the medical profession.

Eventually the biologists organised their own lectures and discussions in zoology, botany, and organic chemistry. The effectiveness of the various classes is well illustrated by the examination results. No biology student passed intermediate B.SC. Of the 4 (20%) who passed, all had studied physics and 2 chemistry.

Dr. Johnson asks[1]: "Is the syllabus too wide or too difficult?" From a student's point of view, in a course lasting one year it is difficult to learn everything in the syllabus thoroughly, and simultaneously to develop scientific reasoning and criticism. Hence it is easy to concentrate upon the mastery of facts alone. Time, rather than a difficult syllabus, seems to be the dominant factor. I understand that some lecturers maintain that such a course as I have described should run for two years; but I believe that the Ministry of Education—which awards grants to some students—holds that the duration of the course should not exceed one year.

Whilst my account supports Mr. Hentschel's[2] belief in the deficiency of training, I should not like to suggest that my experience is typical of conditions generally—but it may be.

Worthing. B. J. LEWIS.

INFLUENCE OF HEART-RATE ON CARDIAC OUTPUT

SIR,—The letter in your last issue from Professor McMichael and Dr. Bayliss, so far from clarifying the issue, obscures it further. The Fick formula of 1880 remained for thirty years an intelligent guess, not amenable to experimental verification, in spite of the efforts of men like Gréhant, Quinquaud, Zuntz, Hagemann, Loewy, von Schroetter, Wolfberg, and Nussbaum. It was not until I devised the method of determining the gas content of the blood in the right heart, by analysing the respiratory gases (the sack method), that it became possible to measure the quantities occurring in the formula—in particular such features as the heart output per beat and per minute, the work of the heart, and the rate of circulation. Since in all such measurements it is essential to standardise conditions and use the most precise methods possible, I do not understand why Professor McMichael lets the patient breathe "oxygen-enriched" air and why he uses a spirometer for the analysis instead of the more accurate type of apparatus designed for respiratory analysis, the errors of which are certainly less than + 10%. The use of small blood samples which can absorb only a few tenths of a millilitre of gas makes it imperative to use apparatus of the highest precision.

Moreover, since Professor McMichael's method involves in any case the shaking of blood samples with air, he might as well use the expired air contained in the sack after using my sack method, and so determine the individual dissociation curve[3] instead of relying on the more or less schematic dissociation curve as given by Bohr and Hasselbalch.

It is indeed well known that tachycardia may be of emotional origin; and for this reason I had assumed that the subjects of Kelly and Bayliss's experiments had come to "complete rest"—physically and mentally. If this precaution was not observed, then there is no cause to wonder at minute-volumes ranging from 2 to 12 litres per minute. The origin of my misgivings this wide range of variation was that it was to have been obtained *under the same experi conditions.*

I fail to see any justification for Professor McMi equating lack of subjective sensation with insensi We know that many organs, such as the gut or the which are anæsthetic, react to insults in their specific way. I would like to know on what evide can be stated that the heart—of all organs! to work "without the slightest disturbance of contr function" in the presence of a catheter.

My principal objection to the methods of Prof. McMichael[4] is that in his important investiga does not use precise research techniques, but co himself with clinical methods, which may indeed highly informative but can hardly claim a great sc value.

If at this stage Professor McMichael is still una grasp the fundamental difference between the "p and "performance" of the heart, I cannot but merely point out that so far from being quibble," it is a matter of elementary physics.

London, W.1. J. PLES

THE SOCIAL ADAPTATION OF INSTITUTIO CHILDREN

SIR,—I can assure Dr. Comfort, who wrote last that very great trouble was taken to secure infor about the social history of the social-institution and about the controls.

As far as the institution children were co careful research was made in the files of the assistance and other relevant committees of the authority which had committed the children tional care; and the data recorded were based records of action taken by the local authority of the relatives of these children. In the case of control group, the homes of the children were visited experienced psychiatric social workers, who took a full social history and who would have been awa any tendency to soften the family history.

In order to match our groups in intelligence we a school in an industrial area where the parents' occ tions were chiefly those of labourers or at the semi-skilled.

Bristol. FRANK BODM

INFANTILE PYLORIC STENOSIS

SIR,—As Mr. Ward-McQuaid and Dr. Porritt p out last week in their excellent review of this di adequate preoperative and postoperative proc are essential if satisfactory results are to be obta In particular, I would like to emphasise with the necessity for the complete correction of dehydration to operation. In the past the importance of this has always been fully appreciated. Even with the surgical skill the operative risks for a dehydrated are very high, and it is quite unjustifiable to sub patient to these extra risks. Experience has taught if on admission to hospital the clinical condition infant is so serious as to necessitate parenteral th but chlorides are present in the urine, a sodium solution of one-fifth the strength of normal adequate to maintain salt requirements. With solutions œdema is very liable to develop.

In the postoperative management, whilst feeding to be adjusted according to the weight and condition of the infant, only small quantities at or two-hourly intervals should be permitted for first 24–48 hours.

Early discharge from hospital is another impor measure in order to minimise the risks of cross-infe

o promote continuation of breast-feeding. In owded industrial areas, however. this practice always desirable or practicable, and under these istances in particular, accommodation for nursing rs, the provision of cubicles for the babies, and a trict nursing technique are essential.

e the cases dealt with by the writers in their cover a period of ten years, the over-all results, y state, do not indicate what is now being achieved : ieir last 59 operations with only 1 death gives a more accurate index.

the Birmingham Children's Hospital during the hree years, 292 infants were submitted to istedt's operation for pyloric stenosis with only ths (a mortality-rate of 1·7%). This is much the figure estimated by Aird and compares very ably with those reported by others. With earlier sis and modern methods of treatment, care, and gement, there is no reason why the mortality should reduced to under 1%.

tment of Pædiatrics and Child Health. J. M. SMELLIE.
University of Birmingham.

THE WRONG DRUG

—Last year you drew attention to the danger stakes when using local anæsthetics.[1]

ne twelve years ago I was on duty as an intern emergency service, Lisbon. A patient, aged about ad complete urinary retention from prostatic trophy. I asked the nurse to fill a syringe with olution of 'Novocain,' and injected some 7 ml. the urethra, blocking the meatus. In less than inutes, the patient developed fibrillary contractions e face. I immediately let the anæsthetic flow rd, but the patient developed cyanosis and conns and died in about five minutes. I found that lution was one of 10% cocaine for ocular instillation. s tragedy was useful to me. May it be so to others.

on. J. CID DOS SANTOS.

HÆMOLYTIC EFFECTS OF MYANESIN

,—I very much regret that my suggestion (that the vo occurrence of hæmolysis should be confirmed roscopically) has caused Dr. Clendon and Dr. old so much annoyance. Those interested may wish fer to my letter (*Lancet*, 1949, ii, 1110) and to the le by Mallinson (*Proc. R. Soc. Med.* 1948, 41, 593 493]). They can then form a dispassionate opinion the validity of Dr. Clendon and Dr. Penfold's ments.

wcastle upon Tyne. M. H. ARMSTRONG DAVISON.

R,—In our original article (*Lancet*, 1947, ii, 387) we ed that after the injection of 'Myanesin' into a wrist and withdrawal of a sample of blood from the cubital fossa, "there was obvious naked-eye hæmo- with myanesin, and this was confirmed by the troscope, which showed oxyhæmoglobin present." s should answer your correspondents' query.

arely, however, the vital question concerning anesin is whether, in view of possible damage to blood kidneys, it is a safe adjunct to anæsthesia. Dr. nstrong Davison is asking for conclusive proof of terious effects before he stops using it. Many anæs- ists have drawn their conclusions from published ounts of fatalities following its use, and have aban- ed it because of strong evidence of toxicity. It is ic indeed to find reports of fatalities in spite of this lence (the last appearing in January, 1949), and to lise that myanesin still finds a use in some anæsthetic partments.

n experienced hands, relaxation can be safely and edily produced with such agents as *d*-tubocurarine d 'Flaxedil': and it would be prudent to limit the use of so dangerous a drug as myanesin to such dangerous diseases as tetanus and strychnine poisoning in which it appears to have a more beneficial effect than the others.

G. E. HALE ENDERBY
London, W.1. J. I. PUGH.

VITAMIN E

SIR,—It would seem from the letters in your issue of Jan. 7 that the controversial subject of the effects of vitamin-E therapy is being still further confused by inaccurate quotation and interpretation of scientific papers. May I suggest that the introduction of a minimum degree of accuracy would be in order ?

In the letter from the Shute brothers [1] it is stated that I am secretary of the Ontario College of Physicians and Surgeons and released a wholesale condemnation of the use of vitamin E in cardiovascular disease to the press, radio, and *Modern Medicine in Canada* in November, 1946. This unfortunately is not so. It happens that the only condemnation of the Shutes' work on vitamin E with which I have been associated was in 1939,[2] when certain experiments were recorded which in no way supported their findings that vitamin-E deficiency disturbed the hormone balance in the body and resulted in an excess of œstrogen. The registrar of the Ontario College of Physicians and Surgeons is my father, Dr. Robert T. Noble.

Department of Physiology, University of Western Ontario, London, Ontario. R. L. NOBLE.

FLATULENCE IN INFANCY

SIR,—Dr. Tanner, according to her letter last week, would have mothers "instructed to bring up *all* the baby's wind during the course of each feed, and not only at the end," and presumably she finds this practicable with her own infant. But many mothers discover that their infants, perhaps more high-spirited, perhaps greedier, or perhaps having more capacious stomachs, unmistakably resent this ritual interruption of their feeds and in their resentment swallow even more air, whereas at the end of the feed they are prepared to coöperate—if coöperate is the right word to describe the passive stolidity with which they await the belch (*N.B.*, English for "burp").

Is the perambulator in part responsible for windy colic in the horizontally resting baby ? In this connection it would be interesting to know if the Red Indian papoose carried vertically on its mother's back ever suffers from wind. It might be hard work for the mother, but it would save about two hours' back-rubbing a day.

St. Mary's Hospital Medical School, London, W.2. J. P. M. TIZARD.

THE FUTURE OF COMMUNITY CARE

SIR,—We were interested in your leading article last week, and welcome its emphasis on the importance of the work of psychiatric social workers.

You suggest that the local authorities may experience difficulty in providing a service of aftercare for ex-mental-hospital patients, as patients "will not bring their intimate personal troubles to a statutory body." This has not been our experience in Leeds. Following receipt of the notice of discharge of a health-service patient, our psychiatric social worker (or mental-health worker) calls on him at home to explain the aftercare service provided and ascertain whether or not the patient wishes to utilise it ; of 356 patients offered assistance in this way during 1949, only 8 rejected it. The acceptance of the service gladly, without suspicion, and without notice of the fact that the social worker is an employee of the local authority may be assisted by the following circumstances :

1. The social worker is in many cases known to the patient and/or his family because a previous visit may have been made

to provide the report for the psychiatrist on the patient's admission to hospital.

2. Accommodation has been provided in the city which is entirely "unlabelled" by any reference to the health department or its mental-health division—which has other separate offices.

The aftercare service includes club activities, library-quiet-room, and games room, and handicraft instruction—all in the accommodation mentioned.

MANSFIELD.—On Feb. 1, at Sevenoaks, Perceval Aubertin Mansfield, B.M. Oxfd, aged 71.

Notes and News

TEACHING POSTS IN BAGDAD

THE Royal College of Medicine of Iraq was founded in [illegible] and last August was granted contingent recognition [illegible] English Conjoint Board after a visit by Lord Moran [illegible] present buildings have been erected since 1930 in the [illegible] of the Royal Hospital in Bagdad (650 beds), and [illegible] instruction is given both there and in the [illegible] Hospital (100 beds). The government of Iraq are [illegible] maintain and improve the standard of teaching in the [illegible] for on its students will depend the quality of [illegible] services. They have therefore asked the British [illegible] to help them to find British doctors to fill the new [illegible] of public health, pathology, pharmacology, anatomy, radiology, and the lectureship in chemistry and [illegible] These teaching posts offer opportunities for research, and clinical material is large and varied. The terms offered [illegible] a basic salary of up to £3600 per annum for the [illegible] and £2400 per annum for the lectureship, for a three-[illegible] contract, which is renewable. Application forms may be [illegible] from the Crown Agents for the Colonies, 4, Millbank, S.W.1; but inquiries about the nature and functions of the [illegible] about conditions in Iraq, should be addressed to the [illegible] East Secretariat, Foreign Office, who will be glad to [illegible] interested candidates.

HOME CARE OF HOSPITAL PATIENTS

WE have already described proposals made by [illegible] Cambridge University Medical School for establishing [illegible] home-care and nursing service.[2] With the consent of [illegible] United Cambridge Hospitals this came into active ope[illegible] last August, with a full-time director accommodated [illegible] Addenbrooke's Hospital. In the ensuing three [illegible] patients were recommended for home care, and 5[illegible] were accepted—38 from surgical wards, 5 from [illegible] wards, 10 from medical wards, and 1 from the radio[illegible] centre. The service has not been limited to the [illegible] Cambridge, but has included the districts of [illegible] Cambridgeshire, Essex, the Isle of Ely, and West [illegible] General practitioners and local health authorities [illegible] coöperated well. In particular, the district nurses [illegible] welcomed the scheme and say that the nursing of [illegible] cases adds interest in their work. The reaction of the p[illegible] has likewise been very favourable and there has been [illegible] evidence of anxiety at being sent home. This succ[illegible] attributed to the completeness of the arrangements and to [illegible] fact that the more sensitive type of patient finds the [illegible] atmosphere quieter and more congenial than that of a hos[illegible] ward among other ill people. The initial difficulties of [illegible] home-care and nursing service have not proved as great [illegible] were expected, and it is hoped to extend it to the [illegible] Cambridge hospitals in the near future.

DEOXYCORTONE ACETATE AND ASCORBIC AC[illegible] IN ARTHRITIS

STIMULATED by the preliminary communication of L[illegible] and Wassén[3] on the treatment of rheumatoid arthritis [illegible] deoxycortone acetate and ascorbic acid Morelli and Pus[illegible] in Naples, have tried this therapy in 5 cases of chronic rh[illegible]toid arthritis, 2 cases of acute rheumatoid arthritis, 1 [illegible] chronic lumbar arthritis, and 2 cases of arthritis def[illegible] They gave deoxycortone acetate 5–10 mg. intramus[illegible] taking care to avoid injection into fatty tissue, and [illegible] acid 0·5–1·0 g. intravenously three minutes later. Im[illegible]ment was noted in all the cases except those of [illegible] deformans, and 1 case of acute rheumatoid arthritis wa[illegible] In 2 acute cases and 4 chronic cases of rheumatoid [illegible] the pain began to decrease 15–30 minutes after the inj[illegible] After one or two hours the mobility of the joints [illegible] and returned to normal where anatomical changes [illegible] prevent it. The patient with chronic lumbar arthritis [illegible] for years had not been able to bend his back, lost his pa[illegible] regained freedom of movement soon after the inj[illegible] The beneficial effect in these cases usually lasted ten [illegible] In one case of acute rheumatoid arthritis pain disapp[illegible] for several days.

REABLEMENT IN AUSTRIA

first conference on a medical or sociological subject held in Austria since the war took place in Vienna from 3 to 26, under the auspices of the Austrian ministry of affairs. It was presided over by Prof. Philipp Erlacher, of the Vienna Orthopædic Hospital, and by Dr. Fuchs Austrian ministry, and was attended by over 300 tes, including physicians, surgeons, welfare officers, overnment officials. Speakers from other countries ed Dr. Howard Rusk, adviser on rehabilitation to the l Nations; Dr. Harold Balme, consultant adviser to nistry of Health; Dr. Harold Nilsonne and Miss Höjer, ckholm; Miss Meyer, secretary of the Swiss "Pro is" movement; and Dr. Braun, head of the Institute ileptics, Zürich. Papers were read on such subjects as n developments in the rehabilitation and care of the ally handicapped in Great Britain; the psychological of rehabilitation; the organisation of welfare work in a, and in Sweden; the rehabilitation and training of tics, spastics, the blind, and deaf-mutes; the rehabilita-nd care of war victims, and of industrial injuries; the are of tuberculous bone and joint cases; the provision ificial limbs; the "Pro Infirmis" movement; and ence in the use of advice bureaux and work agencies e handicapped. In delivering the opening address, alme said that the real genius of modern rehabilitation, ll as of all true welfare work, consists not in what we le to do for the handicapped or disabled man or woman what we succeed in enabling them to do for themselves. ere is a growing interest in Austria in the reablement esettlement of the disabled, largely arising from Professor r's famous clinic in Vienna. A property has been acquired de Graz for developing a reablement and vocational ng-centre for 200 patients, including a special paraplegic This property was formerly a spa, with hot springs and advantages, and it should be ideal for such work. Plans been approved for building dormitories, a gymnasium, ered-in swimming-pool, and workshops of all types.

MEDICAL FILMS

o medical films, of very different types, have lately completed by the Wellcome Film Unit. In each the ography is of a very high order. The first, on insulin, tended primarily for doctors and pharmacists, and ts clearly each stage in manufacture and testing. The ucers have plainly had the usual difficulty in deciding group they are seeking to address. The introductory ages, dealing with physiology, are perhaps oversimple medical audience: not so the production sequence.

is film is in 16 mm. black-and-white, with spoken com-ary; running-time 22 minutes.

e second film, on the hydrodynamics of blood-flow in basilar artery, is the first of a series of research subjects e illustrated in conjunction with the physiology depart-t of St. Bartholomew's Hospital Medical College. It ws, by injection of a blue dye into one axillary artery of the oit, that the blood from each vertebral artery remains on same side in the basilar artery when this is formed by the on of the two vertebral arteries; and at the termination he basilar artery it enters only the homolateral posterior bral artery. When, however, the contralateral axillary ry is obliterated, the blood from the two vertebral arteries es in the basilar artery.

his film is in 16 mm. colour; running-time 8 minutes.

Application for copies should be made to the Wellcome m Unit, 183, Euston Road, London, N.W.1.

---

iversity of Cambridge

On Jan. 28 the following degrees were conferred:

M.A.—A. L. Banks.

* By proxy.

University of London

Prof. Jerzy Neyman, director of the statistical laboratory of the University of California, is to give three lectures on Statistical Problems connected with Medical Diagnosis. The lectures will be held on Feb. 27 and March 6 and 13, at 5.30 P.M., at University College, Gower Street, W.C.1.

University of Manchester

The title of Dr. W. F. Gaisford will in future be "professor of child health and pædiatrics and director of the department of child health."

The following appointments have been made: honorary special lecturer in pathology, Dr. James Davson; lecturer in neurosurgery, Mr. G. K. Tutton; lecturer in venereal diseases, Dr. Robert Lees; clinical lecturer in prosthetics, Mr. Harry McIntyre, M.B.; assistant lecturer in radiology, Dr. G. B. Locke; and assistant lecturer in gynæcological pathology, Dr. A. S. Woodcock.

The following promotions have been made: reader in rheumatic disease and clinical director of the chronic rheumatism research centre, Dr. J. H. Kellgren; reader in obstetrics and gynæcology, Mr. C. Scott Russell; lecturer in surgery, Mr. R. P. Jepson; and assistant lecturer in orthopædic surgery, Dr. J. K. Wright.

Royal College of Physicians of Ireland

On Feb. 3 the following were admitted to the membership of the college: D. C. R. Burrows, J. G. Kidney, Denis McCarthy, W. H. McDaniel, R. M. Pritchard, W. M. O. Purcell, W. J. S. Wilson.

Royal College of Obstetricians and Gynæcologists

At a meeting of the council held on Jan. 28, with Prof. Hilda Lloyd, the president, in the chair, William Wellesley Wilson of Hobart, Tasmania, was admitted to the fellowship.

The following were elected to the membership:

J. A. Bentham, D. W. Briggs, H. M. Carey, Florence J. G. Chouler, Robert Crawford, Reginald Cutts, Thomas Dean, M. S. Ellensweig, H. J. Fisher, Elizabeth M. Harper, W. F. Harper, J. S. Hesketh, Pullat Kalyanikutty, Sarah Macaskill, A. S. Majury, A. T. Marshall, J. D. Martin, J. G. Napier, F. P. Pigott, J. H. M. Pinkerton, C. C. Pretorius, Sangarapillai Rajanayagam, T. M. Roulston, S. A. Scorer, Abdel Himmat Abou Shabanah, Aroon Chandra Sinha, W. A. Souter, Alexander Starritt, George Winchester.

British Tuberculosis Association

The annual conference of the association will be held this year at Christ Church, Oxford, on March 22 and 23. Dr. William Stobie will give the opening address, and other speakers will include Dr. S. Leitner, Dr. F. H Kemp, Dr. E. P. Abraham, Dr. E. Nassau, Dr. J. V. Hurford, Dr. T. A. W. Edwards, Mr. K. S. Mullard, Mr. E. Torning, Dr. H. M. Sinclair, Dr. L. H. A. Hoefnagels, Dr. Carrol E. Palmer, Dr. I. C. Yuan, and Dr. A. Q. Wells.

Teaching Hospital Governors

The Minister of Health has appointed the following doctors to the boards of governors of teaching hospitals:

Royal National Ear, Nose and Throat Hospital.—Dr. Adam Gray.
Middlesex Hospital.—Mr. F. W. Roques.

Arthur Sims Commonwealth Travelling Professor

Sir Reginald Watson-Jones is leaving this week for the first of the three parts of his tour as Sims Commonwealth travelling professor.

In Montreal he will make presentations from the Royal College of Surgeons of England to the Royal College of Physicians and Surgeons of Canada, including a presidential gavel carved by Sir Henry Souttar from a piece of teak rescued from the Hunterian museum after the fire-blitz of 1941. In the University of Toronto Sir Reginald will be guest professor for a week and will give a public address on the Progress of a Half-Century in the Treatment of Fractures. He will work in the recently established medical school of the University of British Columbia, Vancouver, and will speak to the Vancouver Medical Society on the New World of Surgery. Invitations have been accepted to deliver eighteen different addresses on surgical subjects, and the Commonwealth professor will visit the University of Manitoba, Winnipeg; the University of Edmonton; Queen's University, Kingston; the University of Western Ontario, London; Dalhousie University, Halifax; and the medical schools of Montreal, Ottawa, and Quebec.

The second part of the tour, in April and May, will include Singapore, New Zealand, and Australia, with the annual meetings of the Royal Australasian College of Surgeons and the Australian Orthopædic Association. The third part, in the late autumn, will include the Central African colonies, Rhodesia, and the Union of South Africa.

Nuffield Dental Fellowships

One of the aims of these fellowships is to enable graduates in medicine and science to receive training that will qualify them to undertake teaching and fundamental research on dental health and disease. The annual value of a fellowship is between £500 and £800 a year. Further particulars will be found in our advertisement columns.

N.H.S. Prescriptions

After March 1, only prescriptions written on the appropriate official form will be accepted for dispensing under the National Health Service Act; and after April 1 prescriptions on other forms will not be accepted by the pricing offices. *Hitherto unofficial forms have been accepted by pharmacists, who have been credited with the value of these prescriptions.*

Mycological Reference Laboratory

Dr. R. W. Riddell has succeeded Dr. J. T. Duncan as director of this laboratory, which is part of the Public Health Laboratory Service of the Medical Research Council. Specimens for examination for pathogenic fungi should be addressed to the director, Mycological Reference Laboratory, London School of Hygiene, Keppel Street, W.C.1.

The World's Food and Britain's Needs

Lord Boyd-Orr, F.R.S., *will preside at the conference on* this subject which the Association of Scientific Workers is holding at St. Pancras Town Hall on March 4 and 5. Speakers will include Mr. Julian Huxley, F.R.S., Sir George Stapledon, F.R.S., Mr. G. A. Reay, PH.D., Mr. S. A. Barnett, Mr. Ritchie Calder, and Mr. F. Le Gros Clark.

National Foot Health Week

From June 12 to 17 the Foot Health Educational Bureau is holding a foot health week. Sir Wilson Jameson will open an exhibition at the Central Hall, Westminster, S.W.1, on the 12th, and there will also be lectures on foot care and demonstrations of shoe-fitting for children. Further particulars may be had from the bureau, 121, Ebury Street, S.W.1.

Association of Psychiatrists in South West Metropolitan Region

A general meeting of this association will be held at 5 P.M. on Wednesday, Feb. 22, at B.M.A. House, Tavistock Square, London, W.1, to elect council and officers, and to discuss the formation of a psychiatric advisory group. All psychiatrists in the region, whether members of the association or not, are invited to attend.

Surgery on Television

Sir Heneage Ogilvie, with his colleagues, will demonstrate on the B.B.C.'s television programme on the evening of Feb. 20 how an appendectomy is performed. The programme is produced by Andrew Miller Jones and will include a film sequence. A hospital ward and operating-theatre will be set up in the studio.

World Health Organisation

The executive board of W.H.O., *which concluded its fifth* session on Feb. 2, has decided that the results of three technical programmes shall be submitted to the third World Health Assembly next May. These are: (1) thirty-nine international standards for biological preparations; (2) the *International Pharmacopœia*; and (3) the new draft international regulation governing health measures in international trade and travel, which, when adopted, will replace the international sanitary conventions now in use.

Because 12 of the 68 countries which joined the W.H.O. are in arrears with their contributions for 1948 or 1949, or both, the executive board has decided to reduce expenditure *in the present year to* $6,300,000. The second World Health Assembly had set the level at $7,500,000; and this may be restored if the financial position improves sufficiently.

Dr. Raymond Gautier is resigning from the post of assistant director-general of the organisation. In March he will take up an appointment as research director for the International Children's Centre. This is a new foundation of the French government, having as its objective, "the promotion, in the different countries of the world, of the study of problems pertaining to infancy, the propagation of knowledge on hygiene and child welfare, and the technical training of specialised personnel."

Journées Medicales de Broussais, 1950

A course will be held at the Hôpital Broussais, [illegible] Didot, Paris, XIV, on May 19 and 20. Further parti[illegible] may be had from Prof. Jean Hamburger, 29, Boulevard [illegible] Courcelles, Paris, VIII.

Tata Memorial Trust

The trustees of the Lady Tata Memorial Fund [illegible] applications for grants and scholarships for research [illegible] diseases of the blood, with special reference to [illegible] in the academic year beginning on Oct. 1.

Grants of variable amount are made for research expenses [illegible] to provide scientific assistants for senior workers. S[illegible] are awarded as personal remuneration, and are intended [illegible] *for junior investigators working* under suitable direction [illegible] normal value has been £400. Applications must be [illegible] before March 31. The grants and scholarships are open to [illegible] any nationality, and in any country in which it will be [illegible] to make payments in the coming academic year. Further [illegible] and forms of application may be had from the secretary [illegible] scientific advisory committee, c/o Medical Research Council [illegible] Queen Street, London, S.W.1.

Dr. Phyllis Edwards has been granted leave of absence [illegible] the North West Metropolitan regional hospital board [illegible] her duties as consultant anæsthetist to West [illegible] Hospital to spend six months as adviser in anæs[illegible] Copenhagen. She will also visit Aarhus and other [illegible] provincial hospital centres.

Diary of the Week

FEB. 12 TO 18

Monday, 13th

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Prof. John McMichael, Mr. J. H. Milnes [illegible] Chronic Hepatitis.

NATIONAL HOSPITAL, Queen Square, W.C.1
5 P.M. Dr. Helgi Tómasson (Iceland): Reactions of the [illegible] Nervous System to Weather and *Climate* in [illegible] *Cold and* Temperate Zones.

Tuesday, 14th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall, S.W.1
5 P.M. Sir Weldon Dalrymple-Champneys: Und[illegible] —a Neglected Problem. (First Milroy lecture)

UNIVERSITY OF LONDON
5 P.M. (St. Mary's Hospital Medical School, W.2.) Pr[illegible] Bacq (Liége): Metabolism of Adrenaline.

CHADWICK LECTURE
2.30 [illegible] Place, W.1.) Dr. C. [illegible] nation Between the [illegible] e Enterprise in Holland.

ROYAL [illegible] Princes Gate, S.W.7
7 P.M. [illegible] Watson, F.S.R.: Medical [illegible]

INSTITU[illegible] sle Street, W.C.2
5 P.M. [illegible] hology of the Skin.

CHELSEA CLINICAL SOCIETY
7.30 P.M. (South Kensington Hotel, 47, Queen's Gate Ter[illegible] S.W.7.) Superintendent Cuthbert, C.I.D.: Medi[illegible] Aspects of Some Recent Cases.

Wednesday, 15th

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, S.E.5
1.30 P.M. Dr. E. Stengel: Lecture-demonstration.

INSTITUTE OF DERMATOLOGY
5 P.M. Dr. C. W. McKenny: X-ray Technique.

Thursday, 16th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Sir Weldon Dalrymple-Champneys: Undulant [illegible] —a Neglected Problem. (Last Milroy lecture.)

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. J. E. A. O'Connell: Review of 500 Surgically Tr[illegible] Cases of Lumbar Intervertebral Disc Prot[illegible] (Hunterian lecture.)

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 26, Po[illegible] Place, W.1
7.30 P.M. Dr. Joseph E. Smadel: Chloramphenicol and Tr[illegible] Medicine.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Dr. Denis Williams: Neurology lecture-demonst[illegible]

MIDDLESEX COUNTY MEDICAL SOCIETY
2.30 P.M. (Central Middlesex Hospital.) Dr. F. Avery [illegible] Integration of Hospital and Domiciliary Servic[illegible] Sick. Dr. B. Beasley: The Mental Defective at [illegible]

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh
8 P.M. *Prof.* Walter Mercer: Manipulative Surgery.

Friday, 17th

UNIVERSITY OF LONDON
5 P.M. Professor Bacq: Substances which Increase the Sensi[illegible] of Tissues to Potassium Ions.

MAIDA VALE HOSPITAL MEDICAL SCHOOL, W.9
5 P.M. Dr. M. Greaves: Demonstration of Neuropsych[illegible] Cases.

EUGENICS SOCIETY
5 P.M. (26, Portland Place, W.1.) Mr. A. S. Parkes, SC.D., F.[illegible] The Primrose Path—Some Aspects of the Popul[illegible] Problem. (Galton lecture.)

THE CONCEPT OF GENETOTROPHIC DISEASE

: J. WILLIAMS

:D essentially upon recent findings in genetics ochemistry which have not yet been incorporated aedical thought, the concept of genetotrophic : may, we believe, lead to an understanding of diseases whose ætiology is at present obscure.

mical ability to apply the knowledge and skills command is at a high level ; but, as Himsworth has pointed out, " the history of modern know- s concerned in no small degree with man's attempt ıpe from his previous concepts."

ew concept which is fundamental to the one under eration is derived from genetics—i.e., partial : blocks (Mitchell and Houlahan 1946, 1947). , such a block involves a heritable trait charac- by diminution (though not complete failure) of to carry out some specific enzymatic transforma- Since a functional deficiency of this kind may :e the need of the body for some specific nutritional or factors, the existence of such partial blocks can ı why different species of animals require different ties of nutrients. Thus, both rats and dogs can t tryptophane into nicotinic acid, but in dogs nversion is so inefficient that nicotinic acid has ecently been regarded as a separate and distinct onal requirement for them. Whether this particular ıvolves a partial genetic block or not is not known, indicates the type of phenomena which may be ned in this way.

h the advent of our newer knowledge of genetics, ion must be given, in the study of disease, not only external agent causing the affliction but also to ubstrate—the afflicted individual. The concept has entered prominently into medical thinking— of " man " as a highly standardised piece of inery—must be recast to include the realisation deviations from the normal are not infrequent minor but universal and often very important . Williams 1946, 1947a).

th this background we may define a genetotrophic e as one in which the genetic pattern of the ed individual calls for an augmented supply of rticular nutrient (or nutrients), for which there ops, as a result, a nutritional deficiency. Partial ic blocks somewhere in the metabolic machinery are ıbly commonplace in the inheritance of individuals explain to a considerable degree why each person sses a characteristic and distinctive metabolic pat- as revealed by urinary and salivary analyses, &c. mpson and Kirby 1949, Williams et al. 1949a, d c).

APPETITE FOR ALCOHOL

this laboratory alcoholism has been studied in ion to the probable importance of individual meta- traits. The working assumption was made that the ing for alcohol which develops in certain people has ıysiological and genetic basis not entirely different ı that of other special appetites which are under siological control (Williams 1947b).

A study of the appetites of rats and mice for alcohol (Williams et al. 1949c) led to the concept of genetotrophic disease as herein described. This study demonstrated, without serious doubt, that the consumption of alcohol by laboratory animals is a genetotrophic phenomenon.

When given a choice between 10% alcohol and water, individual animals of an ordinary laboratory colony subsisting on ordinary diets exhibit a variety of drinking patterns which are analogous to those of human beings. Some of the animals appear constitutionally to be teetotallers, others moderate steady drinkers, others spasmodic drinkers, others drinkers with mounting appetites, and others again drinkers with a relatively strong appetite even at the start. On the basis of the study of different strains, highly inbred and otherwise, it seems certain that these patterns are genetically controlled.

The drinking patterns of the animals when kept on a stock diet appear to be wholly under genetic control. When the experiment was varied to include changes in the diets, however, it was found that the drinking patterns could be shifted by nutritional means from one extreme to the other. On marginal diets *all* of the rats will eventually consume relatively large amounts of alcohol, but when abundantly adequate diets are used *none* of the animals consumes more than a very small amount. When animals have developed an appetite and are consuming relatively large amounts of alcohol, the supplementation of their diets with abundant amounts of various nutritional factors leads to a prompt abolition of their consumption of alcohol. It is manifest that the nutritional factors necessary to cure " alcoholism " in rats vary from rat to rat and from strain to strain.

These observations are completely in line with the genetotrophic concept. Each animal in an ordinary colony possesses a distinctive metabolic pattern based upon its own characteristic partial genetic blocks and consequent augmented requirements for specific vitamins, amino-acids, or minerals. The individual requirements may cover a wide range of values. One animal (or man) may presumably need for maximum efficiency certain nutritional elements in amounts many times in excess of those needed by others. Since such amounts are seldom encountered in ordinary diets, deficiencies develop. As a consequence of these various specific deficiencies, the " perverted " appetite for alcohol arises. Our knowledge of the physiological nature of appetites is at present nebulous, but there are several ways in which the metabolism of alcohol is linked with the utilisation of vitamins. Prominent among these are the known sparing effect of alcohol on thiamine (Westerfeld and Doisy 1945), the mobilisation by alcohol of vitamin A in the body (Clausen et el. 1941), and the increased urinary excretion of nicotinic-acid metabolites and thiamine when alcohol is substituted isocalorically for carbohydrate in the diet (Butler and Sarett 1948).

On the basis of our studies with rats it seems likely that the basic ætiological factor in human alcoholism is genetotrophic, and that the sociological and psychological factors so generally considered fundamental do no more than precipitate the development of the clinical syndrome. Clinical trials on the treatment of compulsive drinkers are now under way.

ÆTIOLOGY RECONSIDERED

From our observations and on the basis of the genetotrophic concept, the current pessimism concerning the treatment of genetic disease is unwarranted. Further, it seems that not only can a single ætiological factor be manifest in diverse ways according to the individual's genetic constitution, but also various ætiological factors may in different people give rise to what is commonly designated as a single clinical syndrome.

A survey of the list of common diseases of obscure ætiology shows that many have aspects suggesting a genetotrophic origin. Let us consider, for example, some of the facts known about cancer, diabetes, rheumatoid arthritis, disseminated sclerosis, and mental disease.

CANCER

Few people would deny that hereditary factors are involved in the ætiology of cancer. The information available on susceptible and spontaneous tumour-developing strains of mice is convincing evidence of this (Heston 1948). Extreme differences in the incidence of cancer among the various racial groups testify further to this fact (Ackerman and Del Regata 1947): thus cancer of the cervix is rare among Jewish women and has a high incidence among Negro women (Bab 1948). Penile cancer, which is very rare among Jews, accounts for 1·5% of all cancer cases in England, and nearly 19% among the Mongols (Ngai 1933). Many reports of a high familial incidence of cancer are available also; Bateman (1949) reports 8 cases of gastric carcinoma in three generations descending from one person.

Though numerous attempts at nutritional therapy of cancer have been made (Greenstein 1947), there is as yet little genuine evidence of an underlying nutritional defect. But there has never been an attempt to provide simultaneously every nutritional requirement in sufficient amounts to meet the requirements that might arise if genetotrophic needs are several times above those considered normal. Moreover, some evidence strongly suggestive of a nutritional defect does exist. Scott (1949) has shown, for example, that addition of B vitamins to the normal diet of rats increases their resistance to the growth of Jensen's rat sarcoma. Other work has shown that a high riboflavine content in rat liver tends to reduce the chance of development of a tumour (Boyland 1948). It is often if not always true that in a highly metabolically active tumour there is a low level of B vitamins (Pollack et al. 1942) and of the derived enzyme systems—e.g., riboflavine (Shack 1943), nicotinic acid (Kensler et al. 1940), and vitamin B_6 (Cohen 1945). Finally, the wide variety of factors that can induce cancer suggests that they operate through the production of some common effect that induces neoplastic growth. It should therefore be pointed out that, even if the primary factors active in carcinogenesis are very different from a genetotrophic one—e.g., involving a metabolic derangement or an infective agent—treatment based upon the genetotrophic concept might nevertheless be effective.

DIABETES MELLITUS

Diabetes mellitus similarly presents many aspects suggesting a genetotrophic origin. There remains little doubt of a hereditary basis for this affliction, and Harris (1949) has presented evidence that older patients having the milder insulin-insensitive type are heterozygous for the abnormal gene, while younger patients are homozygous. Some 30–50% of all diabetics have a familial history of diabetes, and when one uniovular twin has diabetes, the other invariably develops it. This is not true for binovular twins (Pincus and White 1933). Himsworth (1949) has pointed out that "predisposition to diabetes, hereditary or constitutional, is widespread, and that it is the presence of the environmental factor of diet which is disclosing its prevalence." He further points out the positive correlation of diabetic mortality (in patients over the age of 45) with fat consumption and states that this "does not necessarily mean that fat itself is deleterious, for the consumption of fat may merely indicate other, more important, contingent variables." Various other considerations similarly suggest an important rôle of nutrition in diabetes—the possible rôle of inositol being at present a topic particularly worthy of speculation (Lane and Williams 1948). Dietotherapy in many cases is known to have be effects, moreover, not entirely compatible with present understanding of the diabetes syndrome.

RHEUMATOID ARTHRITIS

Though the evidence for a genetic basis for rheum arthritis is not conclusive, there is a definite incidence. The recent spectacular announcement of results obtained by treatment with 'Cortisone' (pound E) shows that a rather specific biochemical is involved (Hench et al. 1949). The cause of the im- ment of the normal synthesis or function of this sub in the body is unknown at present, but the general tance of the B vitamins in sterol metabolism the possibility of an impairment as the result of tional deficiency (Sweat and Samuels 1948). In certain metabolic interrelations between vitamin B the adrenal cortex are already well known. As in cases, the large number of earlier attempts at nutr therapy have been quite inadequate in the light of present concept of the wide divergence in requirements.

DISSEMINATED SCLEROSIS

Certainly among the most perplexing and most medical problems confronting us today is the of disseminated sclerosis. There can be little that a genetic factor is involved (Arasa 1946, D 1946, McAlpine 1946), that multiple sclerosis invol "biochemical or enzyme abnormality" (McAlpine or perhaps a "toxi-defective process," and that factors may be instrumental in precipitating disse sclerosis and directing its course. There was a incidence of disseminated sclerosis in 8 of (McAlpine 1946); in siblings in 6 cases, in the 1, and in the mother in 1. Other studies have similar incidence. Moreover, vitamin therapy benefit too often for a nutritional ætiological be disregarded. Of McAlpine's (1946) patients run down before the illness; and, though most patients appeared healthy, a minority were in sub health and had experienced malnutrition or weight. It has further been suggested that obesity to have a protective effect, and pregnancy, a conducive to nutritional strain, is known to be a fre precipitating factor.

Demyelination.—Fundamental to disseminated scl is demyelination, which may be duplicated experi- tally in various ways (Hurst 1944). Though lit known about the biochemistry of synthesis and de tion of myelin, it is obvious that a deficiency of one of several nutritional factors would interfere the metabolism of myelin. Experimental demyel has been achieved by interfering with oxidation with cyanide or low oxygen tension. The occ presence of anæmia (Campbell et al. 1947), and the prognostic significance of achlorhydria in dissem sclerosis bring to mind another, albeit very di degeneration of the central nervous system—the bined degeneration of the spinal cord that accom pernicious anæmia, and responds to vitamin B_{12}

Cobalt.—The efficacy of cobalt-containing vita *in combined degeneration in pernicious* anæmia in view of recent observations, a possible asso copper and disseminated sclerosis.

Campbell et al. (1947) reported on a group of were studying swayback in lambs. Swayback is a d ating disease associated with a low blood-copper level pregnant ewe, despite the presence of apparently a copper in the pasturage. (It differs from a similar dis lambs, enzootic ataxia, in which there is inadequate copper.) Of the 7 scientific workers studying the developed a neurological syndrome indistinguishable disseminated sclerosis. Though this fact might seem to the theory of an infection it may equally indicate a nutritional abnormality of the region involved. De sful more recent attempts of Mandelbrote et al. to associate copper metabolism specifically with nation, it still seems worth while to point out that alt-containing vitamin B_{12} is effective in pernicious , where there is similarly no evidence of a nutritional cy of cobalt.

knowledge of the rôle of copper in metabolism is lete. The present recognition of its rôle in the lism of tyrosine, and the impairment of the lism of tyrosine in certain forms of mental disease, r, suggests that copper has special functions in biochemistry. The recent report of the use of rome C, folic acid, and thiamine in the treatment minated sclerosis further suggests the importance itional factors and an impaired oxidative meta- in this syndrome (Roizin et al. 1949). Certainly this nebulous area of association there remains amount of research to be done on disseminated s in the light of the genetotrophic concept.

MENTAL DISEASE

lly, there is such a prodigious amount of data to e combined genetic and nutritional influences in forms of mental disease that an entire volume be written on this topic alone. For many forms nity a genetic basis has long been recognised. ann's (1946) survey shows clearly that schizophrenia genetic basis. Nutritional therapy is an acknow- important concomitant in the treatment of nervous in general, but the genetotrophic concept which e developed has not been applied.

mental symptoms associated with many vitamin cies are impressive arguments for further inquiry: amatic effect of nicotinic acid on the dementia ted with pellagra is a classical example. There ast scattered (and highly inadequate) literature emonstrates the presence of numerous metabolic nalities in mental patients (Hoskins 1946, Bellak but these conditions have generally been regarded chogenic. Such an assumption is hardly tenable light of the intense metabolic activity of the l nervous system and the large proportion of the body metabolism for which it accounts. It is dy to be expected that any nutritional deficiency be readily made manifest in a derangement of the us tissue and reflected in gross distortions of the olism. Brain tissue has been shown to cling ously to its available supplies of vitamins (Salcedo 1948), thus showing the critical need for these olic catalysts. The demonstration by Pincus et al. of deranged adrenal function in schizophrenia, he known existence of interrelations between the al cortex and the B vitamins further testify to the tance of this concept in research in mental disease.

CONCLUSIONS

vould be unwarranted to propose at this time that ne of the afflictions discussed here has a purely otrophic origin. In every case, however, there is lerable reason to suspect that genetotrophic factors t work. In most cases in which metabolism is ged in nature, a partial enzymatic block is involved. ite of this block may often be determined by genetic rs. The activation of this block may be either y genetic or occasioned by infective or other sses. A genetotrophic factor need not thus be the ætiological agent, but it may constitute the basic n for the pathological condition. When such a al genetic block occurs, it stands between the tional elements and other metabolites essential for al biological function.

ich an impediment may be overcome in two ways— supplying the products of the blocked reaction, or ncreasing the nutritional precursors to a concentra- that will deliver adequate amounts of product across the inefficient metabolic step. The former possibility is generally impracticable because of the complexity of the metabolic products; it would theoretically be necessary only in the event of a complete enzymatic block, and such a condition would probably prove too rapidly fatal for its presence to be recognised. The augmentation of the precursors in a partial enzymatic block seems to be the practical answer, if the rationale for this massive type of therapy is recognised. Biological variability, as now understood, makes it inevitable that derangements of the type described often arise. The laws of probability in themselves make it clear that such factors must account for numerous pathological conditions. It seems certain that research along these lines must lead to material progress in the understanding and treatment of diseases which are now little understood.

"... The start of our present difficulty was the usage of the term *general surgery* to describe *that range of operative surgery that is spanned by the technical competence of an individual who calls himself a general surgeon*. ... As long as the range encompassed two or more regions (always including the belly), it was called general surgery. But this division of surgery on the basis of what operations a surgeon performs no longer makes sense. ... It might all be straightened out for the next generation if the word *general* could be torn loose from its subjective roots. ... All technical considerations peculiar to an anatomico-topographic region, including the abdomen, would then become specialty surgery. General surgery for example, would deal with considerations common to all wounds; specialty surgery with wounds of the abdomen, wounds of the chest or of the extremities. But all specialty surgery would be dependent on general surgery. What then would become of the general surgeon? Like the comedian who pulls a long rope across the stage and disappears into the wings only to reappear immediately from the opposite wings pulling on the other end of the same rope, there would be a renascence of the general surgeon, but in the full vigor of youth."—EDWARD D. CHURCHILL, *Ann. Surg.* 1950, 131, 127.

A survey of the list of common diseases of obscure ætiology shows that many have aspects suggesting a genetotrophic origin. Let us consider, for example, some of the facts known about cancer, diabetes, rheumatoid arthritis, disseminated sclerosis, and mental disease.

CANCER

Few people would deny that hereditary factors are involved in the ætiology of cancer. The information available on susceptible and spontaneous tumour-developing strains of mice is convincing evidence of this (Heston 1948). Extreme differences in the incidence of cancer among the various *racial groups testify further* to this fact (Ackerman and Del Regata 1947): thus cancer of the cervix is rare among Jewish women and has a high incidence among Negro women (Bab 1948). *Penile cancer*, which is very rare among Jews, accounts for 1·5% of all cancer cases in England, and nearly 19% among the Mongols (Ngai 1933). Many reports of a high familial incidence of cancer are available also; Bateman (1949) reports 8 cases of gastric carcinoma in three generations descending from one person.

Though numerous attempts at nutritional therapy of cancer have been made (Greenstein 1947), there is as yet little genuine evidence of an underlying nutritional defect. But there has never been an attempt to provide simultaneously every nutritional requirement in sufficient amounts to meet the requirements that might arise if genetotrophic needs are several times above those considered normal. Moreover, some evidence strongly suggestive of a nutritional defect does exist. Scott (1949) has shown, for example, *that addition of B vitamins to* the normal diet of rats increases their resistance to the growth of Jensen's rat sarcoma. Other work has shown that a high riboflavine content in rat liver tends to reduce the chance of development of a tumour (Boyland 1948). It is often if not always true that in a highly metabolically active tumour there is a low level of B vitamins (Pollack et al. 1942) and of the derived enzyme systems—e.g., riboflavine (Shack 1943), nicotinic acid (Kensler et al. 1940), and vitamin B_6 (Cohen 1945). Finally, the wide variety of factors that can induce cancer suggests that they operate through the production of some common effect that induces neoplastic growth. *It should therefore be pointed out that, even if the* primary factors active in carcinogenesis are very different from a genetotrophic one—e.g., involving a metabolic derangement or an infective agent—treatment based upon the genetotrophic concept might nevertheless be effective.

DIABETES MELLITUS

Diabetes mellitus similarly presents many aspects suggesting a genetotrophic origin. There remains little doubt of a hereditary basis for this affliction, and Harris (1949) has presented evidence that older patients having the milder insulin-insensitive type are heterozygous for the abnormal gene, while younger patients are homozygous. Some 30–50% of all diabetics have a familial history of diabetes, and when one uniovular twin has diabetes, the other invariably develops it. This is not true for binovular twins (Pincus and White 1933). Himsworth (1949) has pointed out that "predisposition to diabetes, hereditary or constitutional, is widespread, and that it is the presence of the environmental factor of diet which is disclosing its prevalence." He further points out the positive correlation of diabetic mortality (in patients over the age of 45) with fat consumption and states that this "does not necessarily mean that fat *itself is deleterious*, for the consumption of fat may merely indicate other, more important, contingent variables." Various other considerations similarly suggest an important rôle of nutrition in diabetes—the possible rôle of inositol being at present a topic particularly worthy of speculation (Lane and Williams 1948). Dietotherapy in many cases is known to have b effects, moreover, not entirely compatible wi present understanding of the diabetes syndrome

RHEUMATOID ARTHRITIS

Though the evidence for a genetic basis for rheum *arthritis is not conclusive, there is a definite* f incidence. The recent spectacular announcement results obtained by treatment with 'Cortisone' pound E) shows that a rather specific biochemical is involved (Hench et al. 1949). The cause of the ment of the normal synthesis or function of this in the body is unknown at present, but the general tance of the B vitamins in sterol metabolism the possibility of an impairment as the result of tional deficiency (Sweat and Samuels 1948). *certain metabolic interrelations* between vitamin B the adrenal cortex are already well known. As in cases, the large number of earlier attempts at nutr therapy have been quite inadequate in the light of present concept of the wide divergence in requirements.

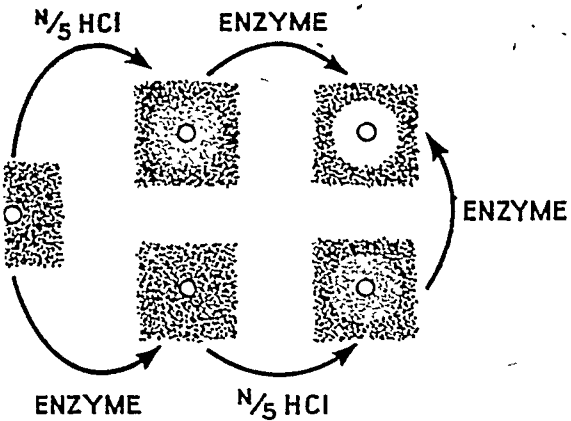
DISSEMINATED SCLEROSIS

Certainly among the most perplexing and mo medical problems confronting us today is the of disseminated sclerosis. There can be little that a genetic factor is involved (Arasa 1946, D 1946, McAlpine 1946), that multiple sclerosis ma "biochemical or enzyme abnormality" (McAlp or perhaps a "*toxi-defective* process," and th factors may be instrumental in precipitating diss *sclerosis and directing its course*. There was a incidence of disseminated sclerosis in 8 of (McAlpine 1946); in siblings in 6 cases, in the 1, and in the mother in 1. Other studies hav similar incidence. Moreover, vitamin therap benefit too often for a nutritional ætiolog be disregarded. Of McAlpine's (1946) patient run down before the illness; and, though mo patients appeared healthy, a minority were in health and had experienced malnutrition or weight. It has further been suggested that obesity to have a protective effect, and pregnancy, a conducive to nutritional strain, is known to be a fr precipitating *factor*.

Demyelination.—Fundamental to disseminated s is demyelination, which may be duplicated exper tally in various ways (Hurst 1944). Though lit known about the biochemistry of synthesis and de tion of myelin, it is obvious that a deficiency of one of several nutritional factors would interfere the metabolism of myelin. Experimental demye has been achieved by interfering with oxidation with cyanide or low oxygen tension. The occ presence of anæmia (Campbell et al. 1947), and the prognostic significance of achlorhydria in diss sclerosis bring to mind another, albeit very di degeneration of the central nervous system—the bined degeneration of the spinal cord that accom pernicious anæmia, and responds to vitamin B_{12}

Cobalt.—The efficacy of cobalt-containing vita in combined degeneration in pernicious anæmia in view of recent observations, a possible asso copper and disseminated sclerosis.

Campbell et al. (1947) reported *on a group of* w were studying swayback in lambs. Swayback is a d ating disease associated with a low blood-copper level pregnant ewe, despite the presence of apparently copper in the pasturage. (It differs from a similar d lambs, enzootic ataxia, in *which there is inadequate* copper.) Of the 7 scientific workers studying the developed a neurological syndrome indistinguishable disseminated sclerosis. Though this fact might seem to the theory of an infection it may equally indicate a nutritional abnormality of the *region involved*. De



-Action of acid and enzymes on dentine powder suspended in agar gel.

between 0·15 and 0·38 mg. per ml. for those of elchii A.

sts were also made with broth cultures of various idia. In all, 26 different strains were used: 5 of elchii A, 5 of *Cl. histolyticum*, 3 of *Cl. septicum*, *Cl. œdematiens*, 2 of *Cl. tetani*, 3 of *Cl. bifermentans*, *Cl. sporogenes*, and 1 of *Cl. butyricum*. The amount zyme produced in an 18–20 hour rabbit liver broth re was estimated by pipetting about 0·1 ml. of re into cups in decalcified dentine agar plates and uring the diameter of the zone of clearing after ours' incubation. Cultures of all the *Cl. histolyticum* ns produced clear wide zones with an average eter of 30 mm. Cultures of all the *Cl. welchii* A ns were also active but were not so potent as those of *istolyticum*; the zones of clearing were from 10 to 20 in diameter. Cultures of *Cl. sporogenes* and *Cl. bifermentans* also contained disintegrating enzymes but gave, 4 hours, only partial clearing in zones not greater 10 mm. in diameter, and after a further 24 hours zones were only slightly more distinct. No enzyme demonstrable with cultures of *Cl. septicum*, *Cl. natiens*, *Cl. tetani*, and *Cl. butyricum*.

bes

robic organisms were also tested for enzyme production. Some of these organisms were chosen because eir gelatin-liquefying properties and others because eir reported presence in carious material. Strains of following, taken from the laboratory stock of cultures, used: *Staph. aureus*, *Ps. pyocyanea*, *Proteus vulgaris*, *p. pyogenes*, *Strep. fæcalis*, *Strep. viridans*, *B. subtilis*, *nycoides*, *B. megatherium*, *B. cereus*, *B. brevis*, and *nthracis*. One strain of *Strep. mutans* (Clarke 1924) one of *Lactobacillus odontolyticus* (McIntosh et al. 2), each from the National Collection of Type Culs, were also included in the tests. The strains were n in nutrient broth or Hartley's broth for 24 or ours, and then tested for enzyme activity by the -plate method. Cultures of strains in the bacillus p were the only ones to produce disintegration of lcified dentine, and gave clear well-defined zones, er greater than 12 mm. in diameter, in which the ticles had undergone complete dissolution. These ve strains were also tested by culturing on nutrient r plates containing decalcified dentine powder. After hours the colonies were sometimes surrounded by a row zone of clearing. Often, however, no zone was ble and this may have been because the rate of ease in colony size during growth was greater than the of diffusion of enzyme through the agar gel, for, n the colonies were washed off the surface of the lium, patches of complete clearing were visible in the as where growth had occurred.

Similar tests are to be made with a larger number of strains of aerobic organisms, especially those in the bacillus group.

ACTION OF ENZYME ON DENTINE

Since *Cl. histolyticum* was found to be the most active producer of enzyme disintegrating decalcified dentine, it was decided to use in tests with dentine a potent ammonium sulphate precipitate from the filtrate of a broth culture of this organism. The precipitate used was one with an average minimal concentration showing enzyme activity (m.e.d.) of 0·008 mg. per ml.

Cups were cut in dentine agar plates and falling dilutions of enzyme solution were pipetted into them. The most concentrated dilution contained 50 m.e.d. per ml. Control cups containing no enzyme were also made and the plates incubated at 37°C. No visible change was observed around the cups containing enzyme, and this was to be expected, for even if disintegration of the organic component had occurred, it might have been masked by the high concentration of inorganic component.

To determine whether enzyme had been active, each cup was filled with $N/5$ HCl. Within 10 minutes a zone of clearing was apparent around each cup and the zones rapidly increased in size, so that in 2 hours they were 20–25 mm. in diameter. The zones were however not completely clear but contained finely divided unaffected particles. No difference could be detected between the density of these particles in the zones around the cups which had contained enzyme and those around the control cups. The unaffected particles in the decalcified zones were shown to be susceptible to the action of enzyme. The whole agar plate was washed in running water to remove the acid and then dried. Enzyme solution containing 50 m.e.d. per ml. was pipetted into each cup and the plate incubated at 37°C. In 3 hours complete dissolution of the particles had occurred within the decalcified zones (fig. 2). This result was confirmed by placing 6 mm. discs of agar, containing dentine particles cut from a dentine agar plate, into a saline solution of enzyme containing 50 m.e.d. per ml. and incubating the solution at 37°C. After 24 hours the agar discs were washed with water and placed in $N/5$ HCl. The particles in the discs were rapidly decalcified but the discs did not become entirely clear because they still contained particles. These particles were found to be susceptible to enzyme action, for, when the discs were washed free from acid and incubated in enzyme solution, complete dissolution of the particles took place.

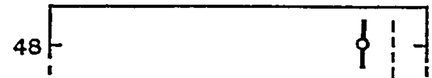


Fig. 3—Relationship between pH and time taken for complete decalcification of dentine particles.

These experiments suggested that *Cl. histolyticum* enzyme could disintegrate the organic component of dentine after it had been released from the inorganic component by decalcification, but not when present in normal calcified dentine.

DECALCIFICATION OF DENTINE IN RELATION TO pH

Though it appeared that *Cl. histolyticum* enzyme could disintegrate dentine only after decalcification, the

DISINTEGRATION OF HUMAN DENTINE BY BACTERIAL ENZYMES

The production by *Cl. welchii* type A of an enzyme which can break down muscle by attacking the collagen of the reticulin scaffolding has been investigated by Macfarlane and MacLennan (1945), Evans (1945, 1947a and b), Oakley et al. (1946, 1948), and Bidwell and van Heyningen (1948). The enzyme has been called collagenase and in-vitro methods have been devised to demonstrate its action and determine its potency. The collagenase was found to be antigenic and immunologically distinct from the other known antigens of *Cl. welchii* A. Recently Oakley and Warrack (1950) have demonstrated that *Cl. histolyticum* also elaborates a collagenase which is antigenic and immunologically distinct from the other known antigens of this organism.

No investigations have so far been reported showing that bacteria produce enzymes capable of attacking the collagen-like matrix of the human tooth, though it has often been suggested that such enzymes play a part in the process of dental caries. In the light of the recent work on bacterial collagenases, it was thought that it might be possible to demonstrate a similar disintegrating effect using as substrate the collagen-like framework of human tooth dentine. In the investigation reported here broth cultures and toxic filtrates of a number of bacterial species were tested for their power to attack both dentine and decalcified dentine. The preliminary results would serve as a basis for investigating the possible rôle of bacterial enzymes in the breakdown of dentine during the carious process in human teeth.

PREPARATION OF DENTINE AND DECALCIFIED DENTINE SUBSTRATES

It was decided to use, as substrates, dentine and decalcified dentine in a finely divided form.

The initial stage of the preparation followed the method used by Atkinson and Matthews (1949). Freshly extracted sound teeth were well washed and dried over calcium chloride for 24 hours, the cementum ground away, the crowns split off and discarded, the root dentine split into small pieces, and the dry pulp removed with dissecting needles.

The dentine was then broken up as finely as possible with pliers, washed thoroughly in water, dried over P_2O_5, and ground for a long time in a ball-mill at a low temperature. The ball-mill used (Mudd et al. 1937) was designed originally for the liberation of labile cellular products of bacteria. It consisted essentially of a metal grinding-chamber containing two stainless-steel balls whose curvature approximated to that of the inner surface of the grinding-chamber. The grinding-chamber rotated at 70 r.p.m. in a freezing bath of solid carbon dioxide and alcohol (−80°C). Chipped dentine in 4–5 g. amounts was ground in the ball-mill at −80°C for 4 hours, by which time the dentine had the consistency of talcum powder. Quantities greater than 5 g. were not so effectively powdered. Water (100 ml.) was then poured into the grinding-chamber and the grinding continued at room-temperature for an hour. The suspension of powdered dentine was then removed from the grinding-chamber, centrifuged, and the deposit dried. This deposit was used as substrate in the tests with dentine powder.

For the preparation of decalcified dentine powder, 4–5 g. of powdered dentine was suspended in 500 ml. of *N*/5 HCl, and the acid suspension was agitated for 4 hours by means of a mechanical stirrer, after which it was centrifuged at 5000 r.p.m. for 15 minutes. The deposit was then resuspended in 500 ml. of water, centrifuged, resuspended in 50 ml. of water, and the final trace of acid removed by dialysis. The sup[illegible] was finally dried from the frozen state and stored in a[illegible] sealed in vacuo. Drying by this method gave a prep[illegible] which could readily be suspended in water. It was [illegible] that the average weight of decalcified dentine was [illegible] that of the dentine and the great bulk of the particles [illegible] about 50 × 50 μ.

For the tests, dentine powder or decalcified [illegible] powder was suspended in an agar gel of neutral pH [illegible] adding 1 ml. of a saline suspension of powder to [illegible] of 4% melted agar in saline. The mixtures were p[illegible] into petri dishes, so that the particles were uni[illegible] distributed, and allowed to set. The concentrat[illegible] dentine was 0·4 g. per 100 ml. of agar and of dec[illegible] dentine 0·1 g. per 100 ml.

DISINTEGRATION OF DECALCIFIED DENTINE BY BACTERIAL ENZYMES

A number of bacterial species were tested for [illegible] ability to produce enzymes which disintegrated dec[illegible] dentine.

Cups of 6 mm. diameter were cut in decalcified d[illegible] plates with a cork-borer, and into each cup about [illegible] broth culture or toxic filtrate was pipetted. The p[illegible] incubated at 37°C. After 24 hours, cultures or filt[illegible] taining disintegrating enzymes gave around the cup a c[illegible] concentric zone completely free from decalcified [illegible] particles, and on incubating for a further 24 hours th[illegible] increased in size (fig. 1). Final readings were made [illegible] after filling the cups. The amount of enzyme pr[illegible] estimated either by titrating falling dilutions or by [illegible] the size of the zone of reaction around the cup.

Clostridia

Dry concentrated preparations of ammonium [illegible] precipitates from toxic filtrates of various or[illegible] the clostridium group were tested. In all, [illegible] toxic preparations were used: 5 from *Cl.* [illegible] from *Cl. histolyticum*, 2 from *Cl. œdemati*[illegible] *Cl. septicum*, 2 from *Cl. tetani*, and 1 from *Cl.* [illegible] None of the preparations from *Cl. œdematiens*, *Cl.* [illegible]*cum*, *Cl. tetani*, and *Cl. sordellii* contained enzyme [illegible] disintegrated decalcified dentine; with each tox[illegible] solution of 40 mg. in 1 ml. of saline gave no cle[illegible] around the cup. Each of the toxin precipitate[illegible] *Cl. welchii* A and *Cl. histolyticum* were active and [illegible] gave clear wide zones in which the decalcified de[illegible] particles had been completely dissolved. These [illegible] were distinctly visible with the concentrated dil[illegible] as early as 2 hours after the cups had been filled, [illegible] at 24 hours the diameter of the zone was someti[illegible] great as 20 mm. and at 48 hours had increased to [illegible] The values for the average minimal concentration [illegible] enzyme activity (m.e.d.) lay between 0·008 and [illegible] mg. per ml. for the toxin precipitates of *Cl. histol*[illegible]

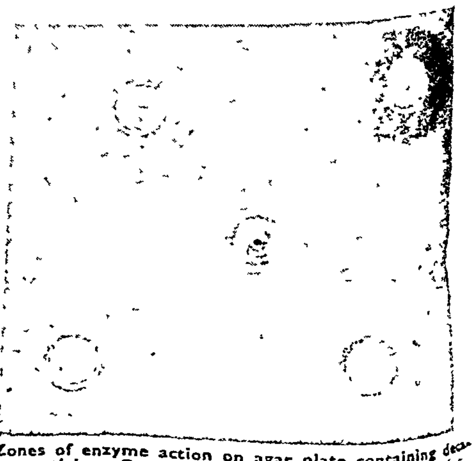

Fig. 1—Zones of enzyme action on agar plate containing dec[illegible] dentine particles. Centre cup contained a culture prod[illegible] enzyme. (Natural size.)

ion at pH 6·4 was completely clear. Those discs at pH nd 6·8 were almost clear at 24 hours and on incubation further 48 hours became completely clear. The discs H 4·0–5·6 were decalcified only, and after 72 hours they contained particles of organic component while those at pH 7·0–8·0 remained unchanged.

CONCLUSIONS AND DISCUSSION

me species of clostridium and bacillus elaborate, ng growth, enzymes which can disintegrate the luble organic component of tooth dentine prepared lecalcification. From the results of tests made with tent enzyme preparation from *Cl. histolyticum* it ears that the organic component when present in nal dentine before decalcification is not susceptible nzyme attack.

ne possibility was considered that the organic comnt might be degraded in some way during decalcifin so as to make it susceptible to disintegration by me. It was found, however, that dentine decalcified ild acid treatment which was unlikely to bring about adation is attacked by enzyme, and thus it is reasonto suggest that the organic component after decalciion is affected by enzyme because the removal of inorganic component has exposed it to enzyme ck. It was also shown that dentine may be simuleously decalcified and its organic component disgrated by enzyme when the pH conditions for lcification are within the range in which enzyme is ve.

has often been suggested that in the process of tal caries bacteria play an important rôle in the kdown of the organic component of the tooth (Pincus 7, 1944, 1947, Frisbie et al. 1944, Frisbie 1945, tlieb 1947, Atkinson and Matthews 1949). Hitherto, ever, there have been no reports of conclusive tests ving that bacteria possess the property of elaborating mes capable of attacking the organic component. as now been shown that some species of bacteria can luce such enzymes, but whether bacteria with similar erties play an important part in dental caries is not wn. This question is to be investigated by culturing ous material on nutrient agar plates containing decald dentine powder. By this method it may be possible isolate organisms producing enzymes which attack organic component.

f proteolytic enzymes are involved in dental caries, if they are of a similar type to the enzyme of *Cl. histocum*, then it seems from our observations that to be ctive their action on dentine must be preceded by or at st simultaneous with the process of decalcification. The alcification process therefore appears to be of primary ortance. Our experiments have shown that solutions ow hydrogen-ion concentration can effect decalcifica, and it is thus possible that many bacterial species h the property of fermenting carbohydrates may y a part in the decalcification of dentine, even though y may not possess the property, shown by *Lactoillus odontolyticus*, of producing high acid concentrans. The possibility that reactions other than bacterial mentation of carbohydrates may be able to effect alcification also needs to be explored. During our estigations we have isolated from dentine a soluble tein which is susceptible to attack by the enzymes ich disintegrate the insoluble protein component, and possibility that the products of enzyme hydrolysis this soluble protein may effect decalcification is being estigated.

SUMMARY

Finely divided dentine powder was prepared from man teeth by the low-temperature grinding of dentine.

ecalcified dentine powder was prepared from dentine wder by treatment with $N/5$ HCl.

An investigation was made of the ability of a number bacterial species to produce enzymes which would disintegrate decalcified dentine powder suspended in an agar gel.

Of the clostridia tested, *Cl. histolyticum* was the most active producer of enzyme, *Cl. welchii* A was less active, and *Cl. sporogenes* and *Cl. bifermentans* were only slightly active.

Of the aerobic species tested, *B. subtilis*, *B. cereus*, *B. megatherium*, *B. brevis*, *B. mycoides*, and *B. anthracis* could produce enzyme, though not in high concentration.

Tests with *Cl. histolyticum* enzyme showed that it was unable to attack the organic component of dentine before decalcification.

Dentine decalcified by mild acid action at pH 6·2 was as susceptible to attack by *Cl. histolyticum* enzyme as dentine decalcified by strong acid solutions.

Dentine was simultaneously decalcified and its organic component disintegrated by solutions of *Cl. histolyticum* enzyme at pH 6·2–6·8.

MANY industrial workers who sustain minor injuries are exposed to oil, dirt, and other contaminants which are not excluded from the wound by the ordinary type of first-aid dressing. To overcome this difficulty, waterproof and other occlusive dressings are now widely used in industrial first-aid stations. In certain industries a waterproof dressing is statutorily required by regulation, and an adhesive wound dressing may be substituted for small and medium-sized sterilised dressings in first-aid boxes.

The advantage of the waterproof or occlusive dressing in preventing contamination of wounds is offset by its ill effects on the wound and the underlying skin. The edges of the wound tend to gape and the underlying skin becomes sodden and macerated, thus delaying healing and sometimes encouraging the patient himself to remove the dressing to " let the air in."

Bull, Squire, and Topley,[1] in 1948, described a new type of occlusive dressing with a 'Nylon' derivative film. Theoretically this overcame the disadvantage of the ordinary type of waterproof covering. Laboratory tests showed that the film is an effective barrier against micro-organisms, but that its permeability to water vapour is sufficient to prevent the skin from becoming sodden. Furthermore, the window in the dressing made it possible to see the progress of healing without disturbing the aseptic barrier. A preliminary clinical trial by Bull question arose whether the concentration of acid used not only released the organic component but in doing so also brought about its degradation so as to make it susceptible to enzyme attack. This question was investigated by testing the action of enzyme on dentine decalcified by solutions of low hydrogen-ion concentration.

---

[1] Bull, J. P., Squire, J. R., Topley, E. *Lancet*, 1948, ii, 213.

To obtain suitable conditions for these tests, it was first necessary to examine the decalcification time at different pH levels. This was done by placing into 10 ml. of each of a number of citric-acid-phosphate buffer solutions (McIlvaine), ranging from pH 3·0 to 8·0, a 6 mm. disc of agar cut from a dentine agar plate. As a control a similar disc was placed in 10 ml. of $N/5$ HCl. After suitable intervals the discs were examined to ascertain the degree of decalcification. It was not possible to decide with certainty, by examining the discs as they remained in the solutions, whether decalcification had occurred, for even with complete decalcification the discs still appeared cloudy because they contained particles of organic component unaffected by acid.

A closer examination was therefore necessary, and this was most conveniently done by removing the discs from the solutions, drying them on filter-paper, and replacing them in the cups in the agar dentine plate from which they had been cut. In this way there was no difficulty in deciding in which discs decalcification had occurred, for the density of the treated discs was compared with that of a background of dentine particles and also with that of the control disc which had been completely decalcified.

The results of this experiment, showing the time taken for complete decalcification in relation to pH, are given in fig. 3. No decalcification occurred at pH 7·0. At pH 6·8 the time taken was 72 hours, and as the pH fell the time of decalcification decreased rapidly until pH 5·5 was reached when on further decrease of pH the time slowly approached zero.

The decalcification time at any fixed pH below 7·0 will obviously depend on the size of the dentine particles. As the particles get larger the time of decalcification will increase and the curve will take on new positions as indicated by the dotted curves in fig. 3. Thus, in making similar experiments with larger dentine particles, the decalcification time at pH values greater than, say, 5·0 may be such that there is no perceptible change in the particles, and this result may give rise to the erroneous impression that decalcification does not occur above this pH.

ACTION OF ENZYME ON DENTINE DECALCIFIED BY MILD ACID

Since the pH conditions for decalcification were now known, it was possible to test the action of *Cl. histolyticum* enzyme on dentine decalcified by mild acid treatment.

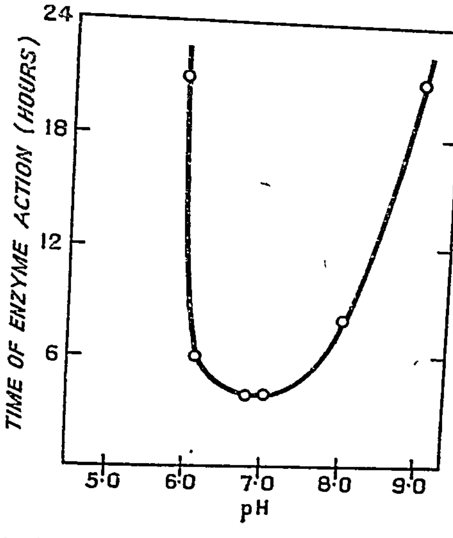

Fig. 4—Relationship between pH and time taken for enzyme to completely dissolve decalcified dentine particles.

Ten discs cut from a dentine agar plate were left in contact with 50 ml. of buffer solution at pH 6·2 for 24 hours, when complete decalcification had taken place. The discs were then washed in water and placed in tubes containing falling dilutions of enzyme in saline. As control, a similar series of enzyme dilutions containing discs cut from a decalcified dentine agar plate was used. Both test and controls were incubated at 37°C for 24 hours, when the discs [illegible] examined. It was found that enzyme had been equally [illegible] in both test and control series, for the minimal [illegible] concentration which showed complete clearing was [illegible] per ml. in each case.

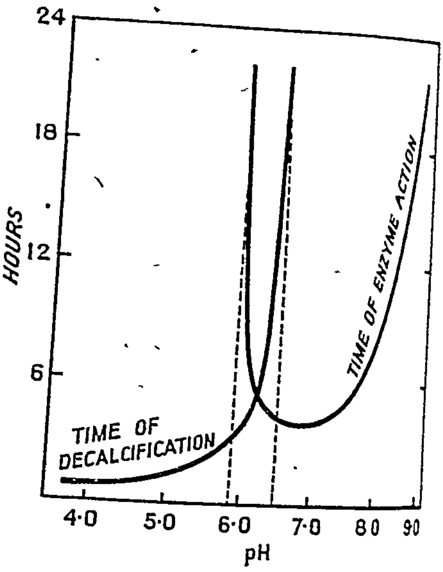

Fig. 5—Curves in figs. 3 and 4 superimposed.

It was evident from this experiment that [illegible] decalcified by mild acid treatment was suscep[illegible] attack by enzyme. It was unlikely that such [illegible] process of decalcification would bring about a [illegible] of the organic component so as to make it [illegible] to enzyme attack, and it was therefore [illegible] suggest that the organic component was [illegible] enzyme because it was exposed by removal [illegible] inorganic component.

ENZYME ACTION IN RELATION TO pH

The question next to be considered was whether [illegible] action and decalcification could occur simultaneo[illegible] It was first necessary to determine the pH range [illegible] which the *Cl. histolyticum* enzyme was active.

Buffered solutions of enzyme were prepared from pH [illegible] to 10·0 so that each solution contained 50 m.e.d. per [illegible] enzyme. Citric-acid-phosphate buffer (McIlvaine) was [illegible] for pH 3·0–7·6 and borate buffer (Clarke and Lubs) for 7·8–10·0. Into 5 ml. of each solution a 6 mm. agar di[illegible] decalcified dentine was placed and the solutions were incu[illegible] at 37°C. Examination of the discs at suitable intervals [illegible] that enzyme action occurred first at pH 6·8 and 7·0 and [illegible] ceeded more slowly at pH levels on either side. After 24 [illegible] incubation it was found that enzyme had been active [illegible] pH range of 5·6–8·9 but not outside this range.

The results of this experiment, showing the [illegible] taken for enzyme to bring about complete dis[illegible] of the particles in the discs in relation to pH, are [illegible] in fig. 4.

SIMULTANEOUS DECALCIFICATION AND ENZYME AC[illegible]

It was now possible to test whether decalci[illegible] and enzyme action could occur simultaneously. T[illegible] curves in figs. 3 and 4 are plotted together in fig. [illegible] the relationship between the two curves sugge[illegible] the most favourable conditions for simultaneous [illegible] cification and enzyme action lay between pH 5·9 and 6[illegible] To test whether this was possible, the follo[illegible] experiment was made.

A series of buffered solutions of enzyme was prepared [illegible] pH 4·0 to 8·0, so that each solution contained 50 m.e.d. [illegible] ml. Into each solution an agar disc, cut from a dentine [illegible] plate, was placed and the solutions were incubated at 3[illegible] Both enzyme action and decalcification occurred bet[illegible] pH 6·0 and 6·8. At 24 hours it was found that the disc[illegible]

Near joint		25 (36%)		27 (39%)

Healing-times.—The average healing-times were :

Nylon	6 04 ± 0 16 days
Waterproof	8 39 ± 0·25 days

This difference is statistically highly significant ($P < 0{\cdot}0001$). The distribution curves of these healing-times are shown in fig. 3. For those cases which healed over the weekend, average healing-times were: for the nylon group 6·45 days, and for the waterproof group 9·65 days ($P < 0{\cdot}0001$). These longer healing-times were to be expected.

The period of the experiment covered eight weeks, and the healing-times over the separate weeks were compared to see if early enthusiasm for the trial was likely to bias the result. The significant difference between nylon and waterproof healing-times still exists, and the differences in nylon healing-times between periods are not significant. But there is a significant difference between the healing-times of the waterproof dressings in the five-day periods. The figure for the last five-day period is high because there were 4 cases with unusually long healing-times. As the healing-times for the *first half* and *the latter half of the investigation* show no appreciable difference it seems that there was no obvious bias caused by enthusiasm for a novel dressing. The average healing-times in days (with the number of cases in parentheses) are given in table VI :

TABLE VI—AVERAGE HEALING-TIMES IN DAYS FOR DIFFERENT PERIODS OF THE TRIAL

Period of Attendance (days) :	*Nylon*	*Waterproof*
1st five	5·21 (14)	8·26 (19)
2nd five	6·23 (26)	8·30 (20)
3rd five	6·11 (19)	7·39 (18)
4th five	6·55* (11)	10·25 (12)
1st ten	5·88 (40)	8·28 (39)
2nd ten	6·27† (30)	8·53 (30)

* 4 days only; † 9 days only.

Effect of contamination, site of injury, and maintenance of seal.—Strangely enough the wounds contaminated with oil appeared to have a shorter healing-time than the apparently clean wounds. As was to be expected, both injuries near the *joint* and those in which the dressing seal was not maintained took, on the average, longer to heal, but none of these factors affected healing-times significantly. Table VII shows the averages for healing-times in days (with the number of cases in parentheses) :

TABLE VII—AVERAGE HEALING-TIMES IN DAYS

	Nylon	*Waterproof*
Wound apparently clean	6·26 (19)	9 06 (18)
Wound contaminated with oil	5·87 (31)	8·07 (30)
Injury near joint	6·12 (25)	8·70 (27)
Injury not near joint	6·00 (45)	8·19 (42)
Seal maintained	5·96 (57)	8·00 (30)
Seal not maintained	6·38 (13)	8·69 (39)

Industrial workers are often heavily exposed to oil and suds and other liquids which tend to get under the adhesive surface of dressings and break the seal. This occurred with the nylon dressings, but their adhesive properties and ability to withstand contaminants compared favourably with the waterproof dressings.

For all finger and hand injuries, including those healing over the weekend, the seal was maintained in 78% of the nylon dressings and 40% of the waterproof dressings (see table VIII). Protective bandages were applied more frequently over nylon dressings, because they were not changed unless the seal was broken and were thus more liable to get dirty ; but when this was taken into account the nylon coverings still showed better adhesive properties.

TABLE VIII—MAINTENANCE OF SEAL

	Nylon	*Waterproof*
Total no. of cases	121	92
Seal maintained	94 (78%)	37 (40%)
Protective bandage applied	96	31
Seal maintained	79 (83%)	15 (48%)
Protective bandage not applied	25	51
Seal maintained	15 (60%)	22 (43%)

Laboratory investigations by Bull (personal communication) showed that a thin film of an oil-resisting synthetic and C. N. D. Cruickshank (unpublished) showed that the dressing was practicable and that wounds under it remained dry and healed well.

Before recommending this dressing for general use it was necessary to make a further clinical trial and to ensure that it could be mass-produced. The type of dressing used in this trial was machine-made, the nylon being coated with adhesive, leaving a clear window to cover the wound (figs. 1 and 2).

The trial was carried out in an engineering works near Manchester, at the invitation of the Medical Research Council's Industrial Medicine Research Unit. The works employs 800 people, mostly fitters, turners, and labourers, who are exposed to contaminants such as oil, grease, rust, metal filings, wood dust, and dirty water. It has a modern treatment-room in the charge of an experienced State-registered nurse, who treated all the cases included in the trial.

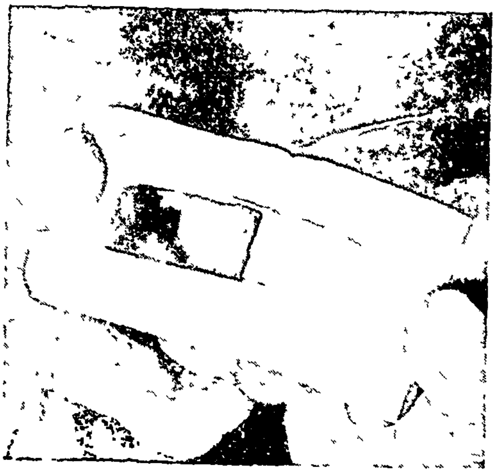

Fig. 1—The nylon dressing.

The trial was planned to assess: (1) the effect on the rate of wound healing; (2) the feasibility of this dressing for minor wounds occurring in an engineering works; and (3) the effect on wound infection assessed clinically but not bacteriologically.

METHOD

Selection of cases.—Assessment was made by comparing the results in approximately equal numbers of wounds treated with (*a*) the nylon-derivative dressing, and (*b*) a waterproof polyvinyl plastic dressing commonly used in industry and approved by the Chief Inspector of Factories (called in this report "the waterproof dressing"). The cases selected were those of all workers with full-thickness lacerations, puncture-wounds, or abrasions, not severe enough to be referred to hospital, who reported for treatment on the day of injury. Injuries to web-spaces and finger-tips were excluded because they cannot be covered satisfactorily with the ordinary type of nylon dressing.

Allocation of cases to groups.—Cases were allocated to the nylon and waterproof dressing groups on alternate days. The use of this method of sampling rather than that of allocating alternate cases to groups made it easier for the sister, who changed the method of treatment daily instead of for each new case. Numbers in each group, though not equal, were of the same order.

Application of dressings.—All wounds were cleaned with cetrimide and the surrounding skin with methylated ether. A no-touch technique was used for all wounds; this was not a theatre technique, but comprised the exclusive use of sterile instruments and dressing swabs. Dressings were applied without further medication and were covered with a bandage where there was risk of contamination, in order to keep the dressing clean. The nylon dressing was left in situ until healing took place. If it became loose or torn, a fresh nylon dressing was applied. The waterproof dressing was replaced after three days, and then daily until healing occurred.

Healing-time.—It was obviously difficult to achieve a reliable and uniform estimate of when healing had taken place. Healing implies a sound cover of the wound sufficiently strong to withstand ordinary strains. The sister recorded each wound as healed only when she was satisfied that the worker could continue his job without a dressing. To some extent the possibility of bias by the sister in favour of one type of dressing was reduced since she had to accept the responsibility of sending her cases back to work without dressings. It was thought that perhaps a different standard of healing would be applied on Friday with a free weekend ahead of the patient, but examination of the numbers regarded as healed on different days of the week showed that no fewer cases were discharged on Fridays than on any other day of the week, and that the nylon cases were not favoured on Fridays.

RESULTS

The total number of injuries treated was 145 for nylon dressings on 19 days, and 129 with waterproof dressings on 20 days. Of these, 6 nylon and 29 waterproof cases were rejected for the reasons shown in table I:

TABLE I—REJECTED CASES

	Nylon	*Waterproof*
Patient did not continue reporting ..	3	3
Dressing came off and another type applied	2	2
Patient changed shift and sister not available	1	3
Patient applied own dressing in middle of treatment	0	20
Wound accidentally hit and reopened ..	0	1
Total	6 (4%)	29 ([illegible])

It is significant that none who had nylon dressings, but 20 with waterproof dressings, applied their own dressing in the middle of the treatment. The latter probably did this to satisfy their curiosity about the progress of their wounds, or because the dressing had come off during the weekend. There was no evidence that these 20 cases were the minor injuries, or that their exclusion was likely to bias the final result. The mean healing-time of finger and hand injuries in this group (9·4 days) was slightly higher than that of the others in the waterproof group (8·4 days).

Table II gives the final figures, classified according to site of injury:

TABLE II—INJURIES BY SITES

	Nylon	*Waterproof*

Healing-times.—The average healing-times were:

Nylon	6 04 ± 0 16 days
Waterproof	8 39 ± 0·25 days

This difference is statistically highly significant ($P < 0{\cdot}0001$). The distribution curves of these healing-times are shown in fig. 3. For those cases which healed over the weekend, average healing-times were: for the nylon group 6·45 days, and for the waterproof group 9·65 days ($P < 0{\cdot}0001$). These longer healing-times were to be expected.

The period of the experiment covered eight weeks, and the healing-times over the separate weeks were compared to see if early enthusiasm for the trial was likely to bias the result. The significant difference between nylon and waterproof healing-times still exists, and the differences in nylon healing-times between periods are not significant. But there is a significant difference between the healing-times of the waterproof dressings in the five-day periods. The figure for the last five-day period is high because there were 4 cases with unusually long healing-times. As the healing-times for the first half and the latter half of the investigation show no appreciable difference it seems that there was no obvious bias caused by enthusiasm for a novel dressing. The average healing-times in days (with the number of cases in parentheses) are given in table VI:

TABLE VI—AVERAGE HEALING-TIMES IN DAYS FOR DIFFERENT PERIODS OF THE TRIAL

Period of Attendance (*days*):	*Nylon*	*Waterproof*
1st five	5·21 (14)	8·26 (19)
2nd five	6·23 (26)	8·30 (20)
3rd five	6·11 (19)	7·39 (18)
4th five	6·55* (11)	10·25 (12)
1st ten	5·88 (40)	8·28 (39)
2nd ten	6·27† (30)	8·53 (30)

* 4 days only; † 9 days only.

Effect of contamination, site of injury, and maintenance of seal.—Strangely enough the wounds contaminated with oil appeared to have a shorter healing-time than the apparently clean wounds. As was to be expected, both injuries near the joint and those in which the dressing seal was not maintained took, on the average, longer to heal, but none of these factors affected healing-times significantly. Table VII shows the averages for healing-times in days (with the number of cases in parentheses):

TABLE VII—AVERAGE HEALING-TIMES IN DAYS

	Nylon	*Waterproof*
Wound apparently clean ..	6·26 (19)	9 06 (18)
Wound contaminated with oil ..	5·87 (31)	8·07 (30)
Injury near joint	6·12 (25)	8·70 (27)
Injury not near joint	6·00 (45)	8·19 (42)
Seal maintained	5·96 (57)	8·00 (30)
Seal not maintained	6·38 (13)	8·69 (39)

Industrial workers are often heavily exposed to oil and suds and other liquids which tend to get under the adhesive surface of dressings and break the seal. This occurred with the nylon dressings, but their adhesive properties and ability to withstand contaminants compared favourably with the waterproof dressings.

For all finger and hand injuries, including those healing over the weekend, the seal was maintained in 78% of the nylon dressings and 40% of the waterproof dressings (see table VIII). Protective bandages were applied more frequently over nylon dressings, because they were not changed unless the seal was broken and were thus more liable to get dirty; but when this was taken into account the nylon coverings still showed better adhesive properties.

TABLE VIII—MAINTENANCE OF SEAL

	Nylon	*Waterproof*
Total no. of cases	121	92
Seal maintained	94 (*78%*)	37 (*40%*)
Protective bandage applied ..	96	31
Seal maintained	79 (*82%*)	15 (*48%*)
Protective bandage not applied	25	51
Seal maintained	15 (*60%*)	22 (*43%*)

Laboratory investigations by Bull (personal communication) showed that a thin film of an oil-resisting synthetic rubber solution applied to the edge of the nylon dressing effectively resisted heavy contamination with oil and maintained the seal. This method has been tried on a small number of industrial workers since the completion of the trial, and has proved to be very effective.

Time saved.—The time saved by using nylon dressings was assessed, taking into account quicker healing and less frequent changes of dressing. The times taken for different dressing operations were:

	Minutes
1. First dressing for both types of covering, including wound cleaning	6½
2. Subsequent change of dressings for both types ..	3
3. Removing protective bandage	½
4. Replacing protective bandage	½
5. Inspecting wound through uncovered nylon dressing	¼

TABLE IX—COMPARISON OF TIME TAKEN IN ATTENDING TO EACH 100 INJURIES WHEN COVERED WITH NYLON DRESSINGS AND WHEN COVERED WITH WATERPROOF DRESSINGS

	Dressing	
	Nylon	*Waterproof*
Protective bandage applied:		
No. of cases	80	34
Average no. of subsequent attendances ..	3·7	5·0
Time taken per case (min.)..	7 + (3·7 × 1) = 10·7	7 + (5·0 × 4) = 27·0
Aggregate of time (min.)	(80 × 10·7) + (18 × 3) = 910*	34 × 27·0 = 918
No protective bandage applied:		
No. of cases	20	66
Time taken per case (min.)..	6½ + (3·7 × ¼) = 7·425	6½ + (5·0 × 3) = 21·5
Aggregate of time (min.)	(20 × 7·425) + (8 × 3) = 172·5†	66 × 21·5 = 1419
Total time (min.) ..	1082·5	2337

* Seal is not maintained in 22% of cases—i.e., 18—and in each of these cases one re-dressing will take an additional 3 min.

† Seal not maintained in 40% of cases—i.e., 8.

Table IX compares the expenditure of time using the two different dressings, and it will be seen that for every 100 wounds dressed the time saved in the treatment-room using nylon instead of waterproof dressings, was approximately 20 hours. Moreover, production time, including time taken in getting to and from the treatment-room, is saved by less frequent attendance for re-dressings. For the purpose of this trial more time than is usual was taken for treating wounds, but the above figures will give some indication of the production time that can be saved by using a dressing which gives quicker healing and allows inspection of the wound without removing the dressing.

Effect on Wound Infection.—Wound infection was assessed clinically and not bacteriologically. All cases in the trial were first treated on the day of injury, and in the great majority treatment was continued until healing had taken place; so it was expected that the number of septic cases would be small. There was in fact only one septic case—a leg wound in the nylon series. The conditions of selection and the use of a no-touch technique by an experienced nurse virtually eliminated the complication of sepsis, and thus the effect of the nylon dressing on wound infection could not be assessed.

PATIENTS' OPINIONS

An attempt was made to get a rough idea of the workmen's opinion of the dressings by questioning all the men (32) treated with nylon dressings in the last fourteen days of the trial. The following questions were asked verbally by the factory welfare officer, who had had no previous interest in the trial and was independent of the factory's medical department: What do you think of the nylon dressing? Has it any disadvantages or advantages over other dressings?

The worker's answers, in his own words, were written down at the time. Answers were unobtainable from 3 men. Of the remaining 29, 17 unequivocally preferred the nylon dressing, 7 were indifferent, and 5 preferred the waterproof dressing. These questions were asked before the synthetic rubber solution had been used to help maintain the seal, and it is worth noting that among the 12 men who expressed indifference or preferred the waterproof dressing, 9 maintained that it did not satisfactorily withstand exposure to oil. Observation of the cases by the sister showed that the nylon covering did withstand oil as well as the waterproof covering. The men's opinions may well have been an expression of their disappointment in a new dressing which, to them, showed the same faults as other adhesive dressings.

THE SISTER'S OPINION

The findings discussed here were generally supported by the sister doing the dressings. She particularly underlined the importance of the time saved. The time spent on treatment is all-important. Prolonged waiting discourages attendances for dressings and thus causes a rise in the incidence of sepsis.

Patients do not like a small cut which at first looks healthy to become white and soggy after it has been covered for a day with the ordinary waterproof dressing. This encourages patients to renew their own dressings in order to allow their wounds to dry, and increases the risk of wound infection. Thus the nylon dressing has a definite clinical value in that it allows both the nurse and the patient to see the condition and progress of the wound.

SUMMARY

A controlled clinical trial of the treatment of minor industrial wounds with a nylon-derivative dressing is described.

The healing-times of wounds so treated was significantly shortened by comparison with similar wounds treated with a waterproof wound dressing commonly used in industry.

The nylon dressing maintained its seal more satisfactorily, particularly when a film of synthetic rubber solution was applied to the edges of the dressing. It was generally preferred by the patients because of the quicker healing and good condition of the underlying skin.

The transparency of the film has great clinical value. The saving of production time by using a dressing which promotes quicker healing and allows a rapid inspection without a re-dressing is considerable.

We are indebted to Dr. J. P. Bull, assistant director, Medical Research Council Industrial Medicine and Burns Research Unit, Birmingham Accident Hospital, for his advice and encouragement in planning and executing the trial; for supplying the nylon dressings; to the plastics division of Imperial Chemical Industries Ltd., Messrs. T. J. Smith & Nephew Ltd., and Messrs. Herts Pharmaceuticals Ltd. for assisting in the development of the nylon dressing; to Dr. Clare Sykes for helpful criticism; to Miss H. N. Mercer for doing the questionnaire; and to the management and employees of the Henry Simon Engineering Works Ltd., whose coöperation made this trial possible.

> "... Wisdom is the result of experience in a man who can profit by it because he has cultivated the ability to use his mind well. Unfortunately for the future, the medical student is a tender plant more often watered with a jet of 'scientific method' than with the gentle rain of culture; so knowledge grows while judgment withers."—HENRY J. L. MARRIOTT, *New Engl. J. Med.* 1949, 241, 968.

.OGESTERONE IN THE TREATMENT OF RHEUMATOID ARTHRITIS

A CLINICAL TRIAL IN 5 CASES

W. R. M. ALEXANDER

MEDICINE, UNIVERSITY OF EDINBURGH

umatic Unit, Northern General Hospital, Edinburgh

ich et al. (1949) reported dramatic remissions of ;oms in rheumatoid arthritis following the adminis- n of ‘ Cortisone ’ in large doses. In view of the ical difficulties and high cost of production of this one it seemed justifiable to attempt an assessment possible therapeutic value of progesterone, a steroid a close structural relationship to cortisone, in a series of cases in the active phase of rheumatoid itis.

ere is evidence of a great increase in progesterone iction during pregnancy (Venning and Browne Browne et al. 1937, Venning et al. 1937), and frequent occurrence of remissions of rheumatoid itis in patients becoming pregnant (Hench 1938) ed to provide additional justification for this

uw and Kuipers (1938) reported encouraging results cases of rheumatoid arthritis treated with com- iively small doses of progesterone. In a larger series, 1 (1949) injected 12 male and 9 female patients with g. of progesterone daily for thirty days. Clinical ovement of various degrees was observed in 15 cases.

CLINICAL MATERIAL AND METHOD

e patients chosen for a trial of progesterone in high ge were 4 women and 1 man. The female patients selected from among those who had passed the opause to avoid the possibility of excessive menstrual ling on withdrawal of the hormone.

ie diagnosis was based on the presence of a poly- ritis of typical distribution, and radiological evidence n arthritis of the rheumatoid type. All were in an ve phase of the disease as indicated by persistent t pain and swelling and mild or moderate hypo- mic anæmia. With the exception of case 2, all had aised erythrocyte-sedimentation rate (E.S.R.) on ated estimation. All were inpatients in the umatic Unit throughout the control and treatment ods.

linical assessment was made by one observer R. M. A.). Detailed charts of subjective symptoms and objective changes were kept, and the hæmoglobin percentage and E.S.R. were recorded weekly or more frequently. From the time of admission the patients were put on a basic régime of treatment, the essentials of which were rest in bed, physiotherapy, and the application of rest splints to the painful joints. An ample well-balanced diet was supplemented with extra milk and vitamin concentrates except in case 4, where an 800-calorie diet was prescribed because of obesity. Patients remained on this régime for control periods of one to five weeks (see table) before injections were begun.

Most cases of rheumatoid arthritis will improve initially in these circumstances, and the control period was thought to be essential to avoid the response to rest and physical treatment being attributed to progesterone. In the present 5 cases, signs of activity, as defined above, persisted and it was considered that an adequate base-line had been established in each case before progesterone was given.

Preparation and Dosage.—Progesterone in oil (B.D.H., 25 mg. per ml.) was administered intramuscularly in the doses indicated in the table. No toxic effects were noted, but in case 1 the affected joints became more painful and swollen during the administration of progesterone.

RESULTS

In no case was there any striking improvement during or after the administration of progesterone. The condition of the joints improved in all cases, but not more so than would be expected from the non-specific measures used throughout. In 4 cases the E.S.R. remained rapid throughout the control period and during the period on progesterone. In case 2 the E.S.R. was normal on admission in spite of considerable pain and limitation of movement in many joints; during the administration of progesterone it increased, returning to normal before the patient's discharge. In the 4 patients who were underweight initially there was no significant gain in weight during or after treatment.

In view of the fall in circulating eosinophils following the injection of adrenocorticotropic hormone (Thorn et al. 1948) and of cortisone (Thorn and Bayles 1949), eosinophils were counted hourly in case 1 after the injection of 100 mg. of progesterone. No fall had occurred at four hours, whereas an injection of 25 mg. of adrenocorticotropic hormone in this case produced a 90% fall. In 5 cases of rheumatoid arthritis not included in this series an injection of 100 mg. of progesterone produced no fall in 4 cases and a 37% fall in 1.

DISCUSSION

Spies and Stone (1949) found that steroids which had no effect on the circulating eosinophils did not produce an amelioration in rheumatoid arthritis comparable to

	F	50	½	1	100	14	1·4	64	64	70	56	56	78	78	80	80	88

Case 1 received two courses of progesterone.
Figures in parentheses indicate estimations carried out four weeks after end of treatment with progesterone.
E.S.R. estimated in Westergren tube with oxalated venous blood (Wintrobe's mixture).
Hæmoglobin estimated on oxalated venous blood with photo-electric colorimeter (100% ≡ 14·8 g. of Hb per 100 ml.).

that reported with adrenocorticotropic hormone. Our experience with progesterone confirms this.

Venning (1946) reported a considerable rise in excretion of corticoids in pregnancy. In the light of recent reports on the beneficial effect of cortisone it therefore seems likely that remissions of rheumatoid arthritis occurring during pregnancy are due to increased production not of progesterone but of steroids with a cortisone-like action. It is of interest, however, to note that the metabolism of progesterone in rheumatoid arthritis appears to be abnormal. After the injection of progesterone the quantity of pregnanediol recoverable from the urine is greater in patients with rheumatoid arthritis than in normal persons (Sommerville et al. 1950).

SUMMARY

Large doses of progesterone were administered to 5 patients with rheumatoid arthritis.

No evidence of therapeutic benefit was obtained.

No fall in the number of circulating eosinophils was noted after the injection of 100 mg. of progesterone.

It is suggested that the remissions of rheumatoid arthritis which occur during pregnancy are not due to progesterone but may be attributable to increased production of other steroids by the adrenal cortex.

We are indebted to Prof. L. S. P. Davidson for his helpful criticism and advice in the preparation of this report.

EFFECTS OF SULPHONAMIDES ON SERUM-PROTEIN, PLASMA VISCOSITY, AND ERYTHROCYTE-SEDIMENTATION RATE

JOHN HARKNESS
M.B., B.Sc. Glasg.
CHEMICAL PATHOLOGIST, CENTRAL LABORATORY, PORTSMOUTH

THE effects of ordinary therapeutic doses of sulphanilamide and sulphapyridine on the serum-protein levels, plasma viscosity, and erythrocyte-sedimentation rate (E.S.R.) have been investigated in normal persons.

MATERIAL AND METHODS

The subjects of the experiments were apparently normal men, aged 20–63, but they were not physically examined. Their lives were restricted to a routine of work, exercise, food, sleep, &c., so as to reduce other physiological stimuli to a minimum and to allow the successive blood samples to be removed under almost identical conditions. To reduce the emotional stimuli, the men were not told on which days blood would be removed, and they were not likely to be mentally disturbed by taking tablets.

Six men were given 2 g. of sulphanilamide by mouth, followed in 4 hours by another 2 g., and thereafter by 1 g. 4-hourly until a total of 20 g. had been administered. With another six men the same procedure was car out with sulphapyridine.

Venous blood was drawn, with minimal stasis, f the fasting men at the same hour of the day. Part the blood was allowed to clot to produce serum, wh was later separated by centrifuging; and part was u to make an accurate 4 : 1 mixture with 3·8% sodi citrate solution.

Clinical pathological estimations were made of serum total protein, by the falling-drop specific-grav technique of Barbour and Hamilton (1926); (2) plas viscosity by the technique of Houston et al. (19 (3) serum viscosity by the same technique; (4) pack cell-volume (P.C.V.) by centrifuging citrated blood capillary hæmatocrit tubes for 1 hour at 3000 r.p. and (5) maximal corrected E.S.R. by the meth described by Houston et al. (1945).

RESULTS

The effects of sulphanilamide and sulphapyri were identical, so only the sulphanilamide results a presented. Figs. 1 and 2 show these results in graph form.

The serum-protein, plasma viscosity, serum visco and E.S.R. had all increased within 48 hours of th administration of the sulphanilamide. (The sulph pyridine tests were done at different time intervals, an the increases were evident within 24 hours of giving that drug.) That these increases are not due to hæmoconcentration can be ascertained from the P.C.V. values, in which the variation is smaller and inconstant, and by making allowance for this variation in calculating the changes in these other values (as has been done for the serum-protein only in fig. 1).

No work has previously been published on the daily variations in the plasma and serum viscosities in response to ordinary physiological stimuli, but my experience indicates that such variations should be less than 1% of the original value. The changes

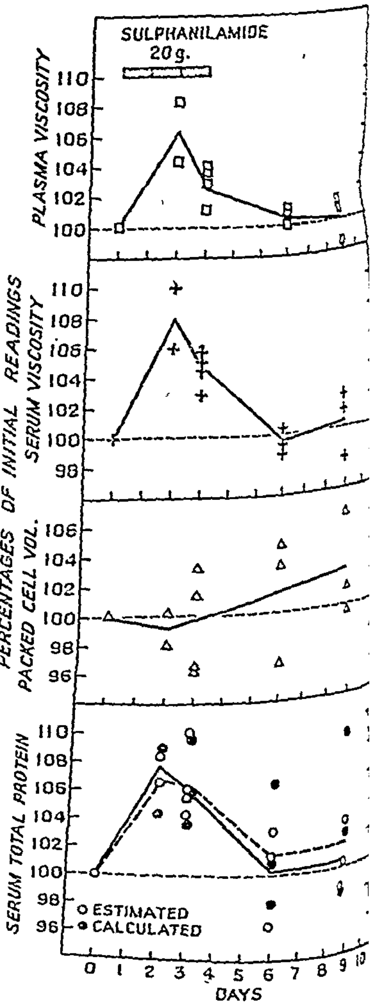

Fig. 1—Variations in plasma viscosity, serum cosity, packed cell volume, and serum-pro on exhibition of sulphanilamide. Results expressed as percentages of values be administration of sulphanilamide. The lines the means of the experimental results.

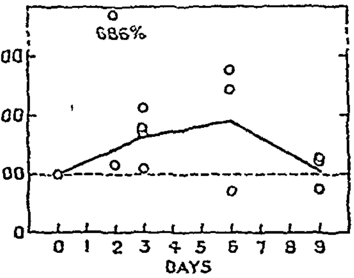
ery instance in this series were greater than 1%; n several instances the change was sufficiently great .ise the plasma viscosity out of the range usually ibed as normal into the range which one associ- with the reaction to organic changes in the body.

DISCUSSION

.e present series of 12 tests is small, but I not had any further opportunity for experiments with these drugs on suitable subjects under suitable basal conditions. The results are offered to draw attention to an effect of the sulphonamides which has not previously been described but seems worthy of further investigation. The .ngs can be discussed from two aspects.



—Variation in erythrocyte-sedimentation ɜ on exhibition of sulphanilamide. Results expressed as percentages of value before ninistration of sulphanilamide. The line ıs the means of the experimental results.

Effects of Sulphonamides on Plasma and Serum

.he interaction of the sulphonamides with the blood- -ein has been described by Davis (1942), but there has ı no mention of any action exerted by them on the unt of the proteins. The increase in *serum-protein* be detected within 24 hours of giving sulphonamides disappears within 3 days of stopping them. From 1 it seems that the effect on *the second day* was ter than on the *third* day—i.e., the protein was nning to fall though sulphanilamide was still being n. This opinion is supported by previous work rkness, unpublished) in which the sulphanilamide administered in similar doses to ten normal persons 10 days and the E.S.R. (Westergren) increased slightly then *returned to normal* while the drug was still ıg exhibited; no such changes occurred when the e routine was *carried* through without giving ɔhanilamide.

.he effect on the protein must be regarded as the mary change in the blood constituents, of which plasma viscosity, the serum viscosity, and the .R. are but reflections. The relationship of the cosity to the protein has been discussed elsewhere ouston et al. 1945, Harkness et al. 1946, Harkness and hittington 1947), as also has the relationship of the .R. and protein (Bendien and Snapper 1931, Fraser d Rennie 1941).

Further metabolic studies should show whether the otein increase is due to increased protein formation decreased utilisation.

) *Significance of Clinical Pathological Tests*

These results also indicate that there is a danger in cepting the changes in the laboratory tests during an ness as being due entirely to changes in the disease ıce sulphonamides alone can produce significant terations in plasma viscosity, serum viscosity, and S.R. Thus, in a case of pyrexia of unknown origin eated empirically with sulphonamides (admittedly ıd therapeutics) the findings after 24 hours might lead a long search for an organic lesion. Furthermore, ıe fall in these values after the second or third day, hether the sulphonamides were stopped or continued ould be interpreted as an improvement in a non-existent isease.

Similarly there has been a division of opinion over the ction of salicylates in rheumatic diseases. While some workers—e.g., Reid (1948)—claim that the E.S.R. is so reliable a test that they are willing to use it as the criterion of amelioration in the rheumatic process, others claim that the salicylates have a direct depressing action on the E.S.R., but no mechanism for effecting the depression has yet been demonstrated.

Before the results of clinical pathological tests can be used for ascribing certain actions to drugs in disease, the effect of the drugs on these tests should be fully studied in normal persons. Nevertheless, there is no guarantee that, in the presence of a disease for which the drug is given, reactions identical with the "normal" ones will be educed.

SUMMARY

The exhibition of sulphanilamide and sulphapyridine to normal persons increased the serum total protein, the plasma viscosity, the serum viscosity, and the E.S.R.

This effect requires further study, but it should be taken into consideration in assessing the significance of changes in these tests in patients under treatment with sulphonamides.

THE MALE FROG (Rana esculenta) PREGNANCY TEST AND ITS CLINICAL APPLICATION

J. BIENIARZ
M.D. Gdańsk
ASSISTANT, OBSTETRICS AND GYNÆCOLOGY CLINIC, MEDICAL ACADEMY, GDAŃSK, POLAND

THERE is a considerable difference of opinion about the value of the male frog, *Rana esculenta*, in the Galli Mainini (1948) test. Hinglais and Hinglais (1948). Biernacka and Pigoń (1948), Fotin et al. (1948), Hernandez Andueza (1948), Aznar Ferreres (1948), and Bach et al. (1949) viewed it enthusiastically, whereas Schockaert et al. (1948), and Hinglais and Hinglais (1949) thought poorly of it.

To assess its value 312 tests were made between December, 1948, and March, 1949—200 with pregnancy urine (114 from normal pregnancies, and 86 from abnormal pregnancies) and 112 controls with urine from non-pregnant persons, all patients in our obstetrics and gynæcology clinic. The pregnancy tests were classified into (1) those done in early (first sixteen weeks) normal pregnancy; (2) those done in advanced normal pregnancy; (3) those done in early (first sixteen weeks) abnormal pregnancy; and those done in advanced abnormal pregnancy.

In this way we could compare results in our groups not only with one another (to see whether they were influenced by the duration of pregnancy or by its abnormal character) but also with those of other workers, who had almost all worked with urine from cases of early normal pregnancy, when the need for a laboratory diagnosis is most imperative.

METHOD

We followed Galli Mainini's (1948) usual technique, except that an amount of urine equal to a twentieth of the frog's body-weight was found sufficient. In this way positive results of varied intensity were obtained, which could be estimated by an approximate count of the spermatozoa in a *droplet* of cloacal urine under

low-power magnification (×100). When the whole microscopical field was closely packed with spermatozoa, and the frog's urine, normally clear, became macroscopically turbid and milky, the result was read as ++++; a similar microscopical picture but with macroscopically transparent urine was read as +++; a density of 20–60 spermatozoa per field was read as ++; and a density of only a few spermatozoa per field as +.

Fluctuations in the reactivity of the frogs have been considered unimportant by all previous workers, though 3–5 frogs have been used for each test to avoid individual differences in reactivity. On the assumption that these fluctuations have a fundamental bearing on the value of *R. esculenta* male frogs in the pregnancy test, we strictly controlled every anomalous result so as to find out the cause of the anomaly. All negative results were subjected to a double control, by injecting the urine under test into 3–5 other frogs, as other workers do, and in addition by injecting pregnancy urine with a known high gonadotropic titre into the frog which had given the negative result. The testes of all frogs which had given false negative results were investigated histologically to discover the cause of non-reactivity. This led to a better understanding of (1) the physiology of spermatogenesis in frogs, (2) the influence of the injections of chorionic gonadotropin on the seminiferous epithelium, and (3) decreased reactivity after repeated injections (see below).

RESULTS

In 156 tests during the first sixteen weeks of pregnancy (normal and abnormal) no false positive and 15 (9·6%) false negative results were obtained. In 92 tests during normal pregnancy at this early period there were only 5 (5·4%) false negative results. Strong positive results in normal pregnancy became less intense between the twelfth and sixteenth weeks, often changing to false negative later. In abnormal pregnancy weak positive or even false negative results were found often in the early period but the results were strongly positive in advanced abnormal pregnancy.

The results are given in detail in the accompanying table. The effects of stage of pregnancy and abnormality of pregnancy are best assessed from the totals obtained in the first sixteen weeks and in the second half of pregnancy in normal and in abnormal pregnancy. It must, however, be remembered that a third factor comes into play—the reactivity of the male frog; this is subject to large fluctuations which are responsible for the weak positive and false negative results in the first sixteen weeks of normal pregnancy.

The number of negative results in the first six weeks of abnormal pregnancy is much greater than [illegible] in the table; there were 52 true negative results in [illegible] of *missed or incomplete* abortion. These 52 [illegible] could not be classed as false negative, because no [illegible] ovum was found in the womb. The total [illegible] of negative results was *thus* 62 in early [illegible] pregnancy.

No pregnancy tests were carried out in the last [illegible] of pregnancy.

DISCUSSION OF RESULTS

Stage of Pregnancy

The observed influence of the duration of [illegible] on the results of the pregnancy tests is expla[illegible] fall in the output of gonadotropin, which is a ph[illegible] phenomenon between the twelfth and sixteen[illegible] of pregnancy (Zondek 1928, Siegler and Fein [illegible] Browne et al. 1939). In abnormal pregnancy—[illegible] abortion and extra-uterine pregnancy—*the fall in o*[illegible] of gonadotropin is a consequence of a [illegible] process separating the ovum from its connections [illegible] the maternal circulation, or decreasing its [illegible] (Zondek 1928, Zondek et al. 1948, Rakoff 1940).

A statistical analysis of the results shows that [illegible] difference between the proportions of false [illegible] results in early normal pregnancy (5 in 92 tests=5·4[illegible] and in advanced normal pregnancy (6 in 22 tests=27·3[illegible] is 27·3−5·4=21·9. Since these groups do not [illegible] belong to the same universe, the standard error of [illegible] difference between the two proportions is shown by

$$\sqrt{\frac{p_1 \times q_1}{n_1} + \frac{p_2 \times q_2}{n_2}}$$

where p is the percentage in the sample in one cat[illegible] and q the percentage in the other category, and n_1, n_2 are the numbers of results in the two samples.

$$S_r = \sqrt{\frac{5{\cdot}4 \times 94{\cdot}6}{92} + \frac{27{\cdot}3 \times 72{\cdot}7}{22}} = \sqrt{95{\cdot}7} = 9{\cdot}7$$

$$\frac{\text{The difference between the proportions}}{\text{The standard error of the difference}} = \frac{21{\cdot}9}{9{\cdot}7} = 2{\cdot}3$$

The difference is more than twice the standard error.

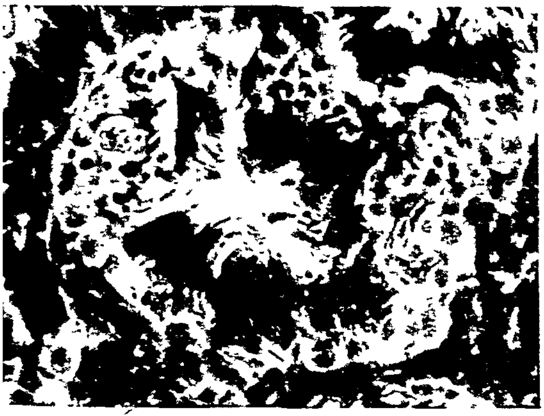
Abnormal Pregnancy

Similarly the difference between the proportions of false negative results in normal pregnancy and abnormal pregnancy is more than twice the standard error of the difference between the two proportions. Statistical principles show that such differences are greater than are likely to arise merely by chance; there is a sufficient experimental basis for the conclusions on the influence of the stage of pregnancy f abnormalities of pregnancy on the intensity and nity of the results of the pregnancy tests.

CLINICAL APPLICATIONS OF TEST

normal pregnancy, where the viability of the ovum ngered, the intensity of the result falls, tending ely to change from a positive result into a negative ble). Therefore the male *R. esculenta* can be used gnosis in abortions and to diagnose death of the A weakly positive result between the fourth and weeks of pregnancy, when normally a strong e result is expected, suggests that some danger ns the ovum. A falling intensity of the results is prognostic significance, and the appearance of anent negative result after such a fall indicates f the fœtus. The prompt response to small changes output of gonadotropin enables one to follow the the ovum at the very time when its viability ging.

xtra-uterine pregnancy positive results may be ed in uncomplicated cases only, but cases coming clinical observation are usually complicated, with or less advanced separation of the ovum from al tissue; consequently the results of the preg- test are negative. The value of the test in agnosis of extra-uterine pregnancy is therefore ionable, since a negative result does not exclude -uterine pregnancy.



Seminiferous tubule from normal testis of *Rana esculenta*, showing atozoa clustered round Sertoli cells. (Hæmatoxylin and eosin, .)

increase in the intensity of a positive result in ancy after the sixteenth week, when normally a ase is observed, may be a sign of some complication as hydatidiform mole, chorionepithelioma, preg- intoxication, or pre-eclampsia, which are usually panied by the production of much gonadotropin.

REACTIVITY OF FROG

statement of Schockaert et al. (1948) that the nating male *R. esculenta* cannot be used for the test. se spermatogenesis is dormant in winter, is not med. Even in winter I have seen mature sperma- clustered upon the Sertoli cells and ready to be sed by an injection of pregnancy urine. The reac- of the hibernating frog may be a little decreased et al. 1949), but this is of no serious importance in al pregnancy before the sixteenth week, when the ntration of gonadotropin in the urine is great gh to cause a good reaction in the frog even in r.

nglais and Hinglais (1949), after reporting favour- (1948) on *R. esculenta*, found the same species isfactory and explained their change of opinion as due to the infestation of the frog's testes with itic protozoa from the rectum. These protozoa, however, live in the alimentary tract and do not invade the genito-urinary tract. In a series of histological preparations I found no protozoa in the testes, though they were present in great numbers in the rectum. Further, the presence of protozoa in cloacal urine never caused the result of the test to be negative.

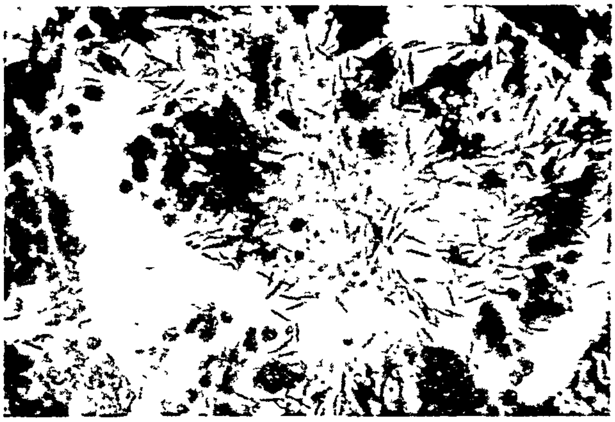


Fig. 2—Seminiferous tubule after a single injection of pregnancy urine, showing mature spermatozoa liberated into the lumen, and developmental forms of seminiferous epithelium also partly liberated. (Hæmatoxylin and eosin, × 375.)

The unfavourable view taken of the use of *R. esculenta* male frogs in pregnancy tests by these workers is probably due to fluctuations in reactivity to chorionic gonadotropin after repeated injections of pregnancy urine, especially with a small stock of frogs or after the breeding season. These facts are explained in the following way.

Rugh (1937) observed that the injection of hibernating male *R. pipiens* with anterior pituitary extract released all mature spermatozoa from the Sertoli cells. De Robertis et al. (1946) found the same with *Bufo arenarum* Hensel. This observation formed the basis for the Galli Mainini (1947, 1948) pregnancy test.

Using *R. esculenta* male frogs for pregnancy tests it was noticed that, besides mature spermatozoa, many different developmental forms—spermatogonia, spermatocytes, spermatids, and atypical immature spermatozoa —were to be seen in the frog's cloacal urine after an injection of female pregnancy urine into its dorsal lymphatic sac. It was observed too that the frequent use of the same frog at short intervals for pregnancy tests diminished its reactivity, until finally it became refractory to chorionic gonadotropin, no spermatozoa being released, whereas fresh frogs behaved normally after injection with the same urine. A slight decrease in

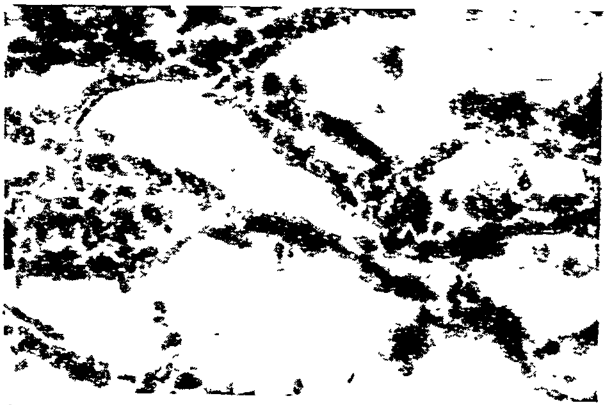

Fig. 3—Seminiferous tubule almost empty after repeated injections of pregnancy urine at short intervals, showing a layer of only 1 or 2 cells on the thin wall. (Hæmatoxylin and eosin, × 375.)

Fluctuations in the reactivity of the frogs have been considered unimportant by all previous workers, though 3–5 frogs have been used for each test to avoid individual differences in reactivity. On the assumption that these fluctuations have a fundamental bearing on the value of *R. esculenta* male frogs in the pregnancy test, we strictly controlled every anomalous result so as to find out the cause of the anomaly. All negative results were subjected to a double control, by injecting the urine under test into 3–5 other frogs, as other workers do, and in addition by injecting pregnancy urine with a known high gonadotropic titre into the frog which had given the negative result. The testes of all frogs which had given false negative results were investigated histologically to discover the cause of non-reactivity. This led to a better understanding of (1) the physiology of spermatogenesis in frogs, (2) the influence of the injections of chorionic gonadotropin on the seminiferous epithelium, and (3) decreased reactivity after repeated injections (see below).

RESULTS

In 156 tests during the first sixteen weeks of pregnancy (normal and abnormal) no false positive and 15 (9·6%) false negative results were obtained. In 92 tests during normal pregnancy at this early period there were only 5 (5·4%) false negative results. Strong positive results in normal pregnancy became less intense between the twelfth and sixteenth weeks, often changing to false negative later. In abnormal pregnancy weak positive or even false negative results were found often in the early period but the results were strongly positive in advanced abnormal pregnancy.

The results are given in detail in the accompanying table. The effects of stage of pregnancy and abnormality of pregnancy are best assessed from the totals obtained in the first sixteen weeks and in the second half of pregnancy in normal and in abnormal pregnancy. It must, however, be remembered that a third factor comes into play—the reactivity of the male frog; this is subject to large fluctuations which are responsible for the weak positive and false negative results in the first sixteen weeks of normal pregnancy.

The number of negative results in the first six[illegible] weeks of abnormal pregnancy is much greater than [illegible] in the table ; there were 52 true negative results in [illegible] of missed or incomplete abortion. These 52 re[illegible] could not be classed as false negative, because no [illegible] ovum was found in the womb. The total num[illegible] of negative results was thus 62 in early abnor[illegible] pregnancy.

No pregnancy tests were carried out in the last [illegible] of pregnancy.

DISCUSSION OF RESULTS

Stage of Pregnancy

The observed influence of the duration of [illegible] on the results of the pregnancy tests is expla[illegible] fall in the output of gonadotropin, which is a ph[illegible] phenomenon between the twelfth and sixteenth [illegible] of pregnancy (Zondek 1928, Siegler and Fe[illegible] Browne et al. 1939). In abnormal pregnancy—[illegible] abortion and extra-uterine pregnancy—the fall in [illegible] of gonadotropin is a consequence of a [illegible] process separating the ovum from its connections [illegible] the maternal circulation, or decreasing its viabi[illegible] (Zondek 1928, Zondek et al. 1948, Rakoff 1940).

A statistical analysis of the results shows that [illegible] difference between the proportions of false neg[illegible] results in early normal pregnancy (5 in 92 tests=5·4[illegible] and in advanced normal pregnancy (6 in 22 tests=27·3[illegible] is 27·3−5·4=21·9. Since these groups do not ex[illegible] belong to the same universe, the standard error of [illegible] difference between the two proportions is shown by

$$\sqrt{\frac{p_1 \times q_1}{n_1} + \frac{p_2 \times q_2}{n_2}}$$

where p is the percentage in the sample in one cat[illegible] and q the percentage in the other category, and n_1, n_2 are the numbers of results in the two samples.

$$S_r = \sqrt{\frac{5\cdot4 \times 94\cdot6}{92} + \frac{27\cdot3 \times 72\cdot7}{22}} = \sqrt{95\cdot7} = 9\cdot7$$

$$\frac{\text{The difference between the proportions}}{\text{The standard error of the difference}} = \frac{21\cdot9}{9\cdot7} = 2\text{[illegible]}$$

The difference is more than twice the standard error.

Abnormal Pregnancy

Similarly the difference between the proportion[illegible] false negative results in normal pregnancy and [illegible] abnormal pregnancy is more than twice the standar[illegible] error of the difference between the two proportions. Statistical principles show that such differences [illegible] greater than are likely to arise merely by chance; [illegible] there is a sufficient experimental basis for the conclusions on the influence of the stage of pregnanc[illegible] ems justifiable, however, to attempt direct laryngo- in all such cases where the respiratory embarrass- cannot otherwise be relieved, and tracheotomy d be done only when this manœuvre fails.

e sedation of these patients, who are extremely ss and of necessity using their accessory muscles spiration, requires care. Respiratory depressants, as morphine, must not be used, at least until an uate airway has been established. Hewer[3] points he very real dangers of intravenous barbiturates in ratory obstruction, and emphasises the necessity n adequate local application of cocaine or other ce analgesic before instrumentation is attempted.

SUMMARY

hæmophilic man with severe respiratory obstruction ting from a pharyngeal hæmatoma recovered after t laryngoscopy and intubation.

n attempt is made to justify intubation in preference racheotomy for such cases.

am indebted to Dr. A. E. Clark-Kennedy, F.R.C.P., Mr. A. Bowen-Davies, F.R.C.S., for permission to publish case.

KIDNEY EXPOSURE THROUGH THE TWELFTH RIB

C. PATRICK SAMES
M.S. Lond., F.R.C.S.
STANT DIRECTOR, SURGICAL UNIT, ST. MARY'S HOSPITAL, LONDON

HE *indications for exposing the kidney by the retro-* toneal approach through the loin are well established, the details of the operation are by no means standard- —the incisions used vary from the nearly vertical Iayo to the more oblique of Morris.

ll these loin incisions have in common certain short- ings, which are eliminated by exposure of the kidney ough the bed of the last rib. This approach has so ny advantages that it is surprising it has not received er recognition. Though practised by a few British logical surgeons it is not described in any standard tish work on operative surgery or urology. The t account of it in English was by Hess (1939), and it s later described by Digby (1941). Robinson (1947), a presidential address at the Royal Society of Medicine, oke of fourteen years' experience with this kidney proach, and he cited Von Lichtenberg as having actised it. A comparable approach was described Hertz (1927) for exposing the suprarenal gland and s been used latterly by many surgeons for operations the splanchnic sympathetic. Egon Wildbolz (personal mmunication) states that he and his father, the late of. Hans Wildbolz, have used this approach to the lney for more than thirty years, but neither they r Von Lichtenberg have ever written about it.

THE OPERATION

The patient is placed in the customary kidney position, th a rigid support beneath the lower ribs, which facilitates e exposure. The length of the patient's last rib is checked diographically, for when this is unduly short care is needed avoid mistaking the 11th rib for the 12th.

The incision is made over the last rib, starting an inch medial the lateral border of the erector spinæ and continuing in the me line beyond the tip of the rib to a point depending on e length of the last rib; an extension of $2^{1}/_{2}$–3 in. beyond is usually suffices with a rib of average length and a kidney normal size. The wound is deepened through the latissimus orsi and serratus posterior inferior muscles down to the b; it is advisable to nick a few of the outermost fibres of the ector spinæ. The exposed portion of the rib is resected bperiosteally; freeing of the extreme tip from the attached

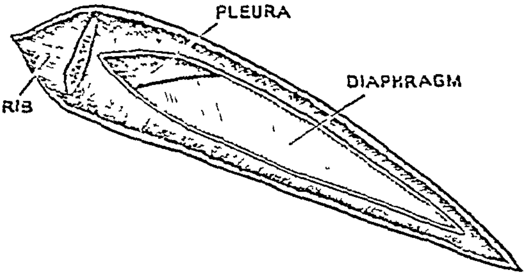

Fig. 1—Relation of pleura to 12th rib bed after incision of posterior periosteum of rib.

muscles and periosteum requires a little patience. The periosteum *of the rib bed is then incised, with special care at* its medial part where the horizontal fold of the pleura is sought and found. The pleura, occupying the inner and upper angle of the rib bed (fig. 1), is deliberately but easily dissected free and displaced from the line of further incision. The lowest fibres of the diaphragm are then incised in the same line and the extrarenal fat and fascia immediately become visible. The incision through the external oblique, internal oblique, and transversalis muscles is extended outwards from the outermost part of the rib bed for a variable distance—usually $2^{1}/_{2}$–3 in. This extension must be in strict line with the continuation of the rib; if it tails downwards at all, the subcostal nerve or some of its branches may be endangered. Once the perinephric plane is found, this outward extension through the muscles is facilitated by cutting down on to two fingers of the left hand placed inside the wound. In the outer angle care must be taken not to damage the reflected fold of the peritoneum, which must be stripped away as required. The perinephric fascia (Zuckerkandl) is incised, and the kidney freed from its perinephric fat.

ADVANTAGES

Access

This approach is anatomically sound. The last rib is one of the normal posterior relations of the kidney, and *on the left side closely approximates to the hilum* (fig. 2); not uncommonly the kidney occupies an even higher position. It is more rational to come down directly on to the organ than to approach it from below. With the more classical incisions great difficulty is often experienced in freeing the kidney from the perinephric fat, owing to the dense strands of fibro-fatty tissue which anchor the upper pole. Because of poor exposure, attempts are made to mobilise the last rib by dividing the lumbocostal ligament (not the external arcuate ligament as is suggested in some textbooks of operative surgery). Forceful retraction is then employed, and often resection of the rib is finally resorted to. It has also been recommended that the outermost fibres of the quadratus lumborum be nicked in the upper angle of the wound. It is during these additional manœuvres that the pleura and subcostal nerve may be damaged, and troublesome hæmorrhage may ensue.

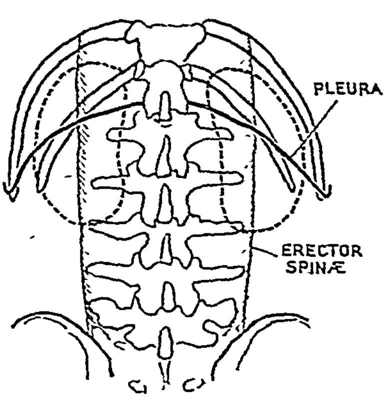

Fig. 2—Relation of pleura and edges of erector spinæ muscle to kidney and 12th rib.

With exposure through the rib bed the kidney can be handled with ease, and nephrolithotomy or other procedures can be performed without delivering the kidney reactivity was also observed in May and July after the breeding-season.

---

[3] Hewer, C. L. Recent Advances in Anæsthesia and Analgesia. London, 1948.

Frogs' testes were examined histologically after single injections of pregnancy urine and after multiple injections given at short intervals. Some of the findings are shown in figs. 1–3. After a single injection of pregnancy urine mature spermatozoa were released (fig. 1), as stated by Rugh (1937) and De Robertis et al. (1946), but sometimes spermatocytes and spermatids were also liberated (fig. 2). After repeated injections of pregnancy urine at short intervals almost all the seminiferous epithelium was shed from the tubules, leaving only one or two layers of thin cells.

These observations explained both the appearance of developmental forms of the seminiferous epithelium in the cloacal urine and the fluctuations in reactivity. A testis exhausted either experimentally by repeated injections of pregnancy urine or physiologically by the breeding-season cannot react normally to the injection of chorionic gonadotropin unless time is allowed for the regeneration of the seminiferous epithelium. Consequently all negative results of the pregnancy test must be strictly controlled when *R. esculenta* male frogs are being used, especially when only a small stock of frogs is available and after the breeding-season. The need for such controls, however, can be avoided by allowing an interval of at least two weeks between tests on the same frog. The best way of working is with a large supply of fresh frogs, of which 3–5 are used for each test to compensate for possible individual fluctuations in reactivity.

PREGNANCY URINE AND PARASITES OF FROG

Interesting observations were made, during these investigations, on the influence of chorionic gonadotropin on the reproductive cycle of certain parasitic protozoa living in the frog's rectum. After a frog had been given an injection of pregnancy urine, the asexual multiplication of the protozoa by fission changed to sexual reproduction with the appearance of encysted forms. This change is similar to that which takes place during the frog's breeding-season, when it is probably caused by the frog's pituitary gonadotropin. It is an example of a biological action exerted by a hormone of vertebrates on invertebrates.

SUMMARY

The *Rana esculenta* male-frog pregnancy test is simple, quick, reliable, cheap, and easily read, provided that all negative results are strictly controlled.

The adverse opinions of some workers are due to fluctuations in the reactivity of the frogs to chorionic gonadotropin.

Some clinical applications of the test for diagnostic and prognostic purposes are pointed out.

RESPIRATORY OBSTRUCTION IN HÆMOPHILIA

RECOVERY AFTER INTUBATION

W. H. F. Boyd
M.B. Aberd., D.A.
SENIOR REGISTRAR ANÆSTHETIST, LONDON HOSPITAL

SPONTANEOUS submucosal hæmatomas in the pharynx and larynx are uncommon in hæmophilia; but, if they develop, respiratory obstruction may constitute a very grave emergency. Davidson et al.[1] in a clinical study of 40 cases of hæmophilia, report a death from the rapid development of submucosal pharyngeal and laryngeal hæmatomas which blocked the airway before treatment could be given. Baird and Fox[2] collected 7 instances of this complication; 4 of the patients recovered without tracheotomy, and 3 died after it. In their own case tracheotomy within five hours of the onset saved the patient.

The onset may be characterised by sore throat and loss of voice, and a hæmatoma may be seen as an obvious swelling on the posterior pharyngeal wall, though more commonly it can only be seen on direct laryngoscopy.

Though in most instances pharyngeal hæmatomas seem to be spontaneous, Baird and Fox[2] point out that over-vigorous use of the voice may predispose to them and suggest that hæmophilics should be warned of this possibility.

CASE-RECORD

A known hæmophilic man, aged 57, was admitted to the London Hospital with severe respiratory obstruction. His wife, who accompanied him, could throw no light on the cause of his present condition; she enumerated [illegible] hæmophilic crises which he had had in the past, but these did not include subpharyngeal hæmorrhage.

On admission the patient was cyanosed and semiconscious, and his greatest respiratory efforts only permitted minimal tidal air exchange. There was extensive swelling on the right side of his neck.

Treatment.—Oxygen was administered through a B.L.B. mask, and great difficulty was experienced in setting up a blood-transfusion owing to the patient's violent struggling. In spite of a pharyngeal airway and oxygen he remained cyanosed and showed little, if any, improvement. It was decided that direct laryngoscopy should be attempted, both to ascertain the extent of the swelling and to ensure an adequate airway through a large endotracheal tube. The mouth was sprayed with 10% cocaine solution, and the fauces, tongue, and piriform fossæ were painted with the same solution by means of Krause forceps. An attempt was next made to introduce a Magill laryngoscope, but owing to the patient's restlessness it was thought that the risk of injuring the pharyngeal wall with the blade and thus causing hæmorrhage was greater than the acknowledged risk of giving soluble thiopentone in the presence of respiratory obstruction. Accordingly, after soluble thiopentone 0·3 [illegible] had been injected by a colleague, a no. 10 Magill oral tube lubricated with 2% 'Nupercaine' ointment was passed under direct vision. Respiration at once became quiet, and the cyanosis disappeared. The tube was left in place for thirty-six hours, by which time the hæmatoma had partly resolved and the tidal air volume was satisfactory. Further convalescence was uneventful, and the patient was discharged from hospital in three weeks.

DISCUSSION

Tracheotomy has been done in a few cases of pharyngeal and laryngeal hæmatomas complicating hæmophilia, but the results, even with blood-transfusion, have been unsatisfactory.[2] Laryngoscopy also is not without risk, and the chances of injuring the already swollen and distorted mucosæ over the hæmatomas are considerable.

was adjusted with acetic acid to between as then concentrated so as to bring down r 50 ml. In ten cases this was done at by placing the urine in a large, shallow nder a powerful fan; this process was in less than 48 hours. In two cases, the s done by vacuum-distillation at 40°C; ver, was found to be no less time-consuming. urine was then enclosed in a 'Cellophane' against distilled water until it was free from volume of the concentrated dialysed urine up to exactly 50 ml.

a 24-hour specimen of urine from a normal s collected simultaneously under toluene, and ated and dialysed in exactly the same way. of this urine was also made up to precisely 50 ml.

ntidiuretic potency.—The method employed for e was that recommended by Burn.[12] Groups of albino rats, each weighing 120–150 g., were used t. To each animal 5 ml. of water per 100 g. body- as administered by stomach-tube; a no. 3 size theter, dipped in glycerin, was used for this purpose. was held vertically by an assistant and a small wooden h a central hole was inserted across its mouth. The as then gently passed down into the stomach, using rce. A 10 ml. syringe was fitted to the distal end of be and an exactly measured volume of water (5 ml. 0 g. body-weight of the animal) was injected down the The tube was then withdrawn and 1 ml. of the ssed" urine per 100 g. body-weight was injected aneously into the animal—the patient's urine for the nimals and the normal urine for the controls. The l and test groups (each of four animals) were then to two separate cages. These cages were provided with loors of large mesh and had a wide funnel attached bottom, to conduct the urine to a measuring cylinder below.

time at which the rats received water and were injected corded. The time at which excretion of urine from each as noticed was also recorded. The volume of urine collected from each cage was recorded every 15 minutes for about 4 hours.

After the lapse of 48 hours, the groups were interchanged and the test was repeated; this was to avoid possible errors due to differences in the sensitiveness of the animals.

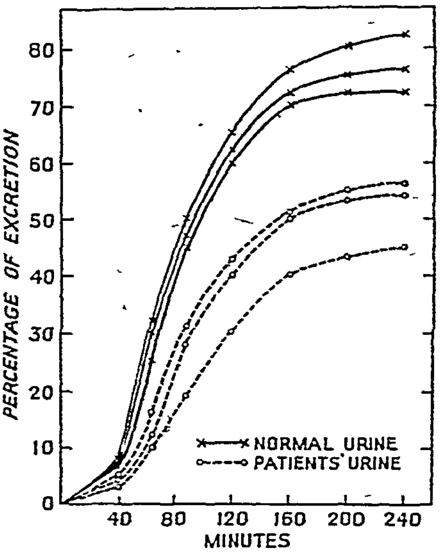
e results were treated by the "t" test, and the differences e percentage of excretion between the control and test groups found to be significant.

RESULTS AND DISCUSSION

It was observed that while rats injected with normal urine excreted on average 72·5% of the ingested water in 4 hours, those injected with urine from cases of nutritional œdema excreted on average only 47·6% of the ingested water during this period. The results are set out in the accompanying table and figure.



Thus in the non-dialysable fraction of the urine from cases of nutritional œdema there is obviously some factor which promotes anti-diuresis and water-retention. The actual nature of this antidiuretic substance is a subject for further investigation. Robinson and Farr[13] demonstrated an antidiuretic substance in the urine of patients with premenstrual œdema. On the other hand, Ralli et al.[11] demonstrated increased urinary excretion of an anti-diuretic factor in cases of hepatic cirrhosis with ascites; this was attributed to failure of the damaged liver to destroy a 'Pitressin'-like factor. Drill and Frame[14] have confirmed this observation. Leslie and Ralli[15] showed that rats given a low-protein high-fat diet for two or three weeks also excreted in the urine increasing quantities of the antidiuretic factor. This was observed long before such diets produced hepatic cirrhosis, and was attributed to impairment of liver function by fatty infiltration. That starvation and protein depletion damage the liver has been shown by several workers.[16–19] It is possible that such damage may not always be clinically detectable. Like the pitressin-like factor demonstrated by Ralli et al.[11] in cases of hepatic cirrhosis, this substance was active at a pH range of 4–5.

Several workers have shown that the antidiuretic effect of posterior-pituitary extracts is associated with increased excretion of chlorides.[20–23] Preliminary observations indicate that in the cases recorded here the antidiuresis is not associated with such increased chloride excretion. Ralli et al.[11] have, however, pointed out that the chloruretic effect of pitressin is lost after dialysis.

It has been suggested that dehydration might cause the appearance of antidiuretic substance in the urine.[23]

from the wound. However, if delivery is required it is facilitated by the adequate exposure and it will be still easier if an assistant presses on the abdomen; this manœuvre tends to squeeze the kidney upwards and outwards through the wound, whereas with the other loin incisions it usually forces the kidney still further under the overhanging last rib.

Kidney exposure is usually difficult in patients with a reduced iliocostal gap, whether this is a result of scoliosis, an unduly long 12th rib, or a general squat stature. Exposure through the last rib bed overcomes all such difficulties, for even in the very fat or muscular patient the final wound seems to be less deep than it would be with the more classical approach.

The Pleura

In surgery it is axiomatic that when damage to an important structure is feared, that structure should be clearly visualised and then avoided. The relation of the fold of the pleura to the 12th rib bed is illustrated in fig. 1; minor variations are found (Melnikoff 1923), but these are of no practical importance provided that the pleura is sought for and carefully pushed away by delicate dissection. With other loin incisions, damage to the pleura usually results from efforts to improve an inadequate exposure. Hess (1939) makes no attempt to excise the rib subperiosteally and advised "tearing the transversalis fascia with the fingers" so as not to endanger the pleura—surely a most unsound procedure.

The Subcostal Nerve

The course of the subcostal nerve varies in obliquity, and consequently it is endangered in the classical loin operations. By many surgeons it is boldly severed and the consequent muscle weakness and anæsthesia are disregarded. Some accept an area of anæsthesia "the size of the palm of the hand" as a regular accompaniment of kidney operations. When the kidney is approached through the rib bed, the line of incision is essentially segmental between the 11th and 12th myotomes; the subcostal nerve always lies at a more distal level and is out of danger whatever its variations. The approach thus protects the nerves from damage, and it also appreciably reduces the amount of bleeding.

WOUND CLOSURE AND HEALING

Hernia is by no means rare as a complication of kidney operations. This is not surprising in view of the extensive muscle cutting involved, and an additional factor is probably the difficulty of suturing in the lower angle of the wound because of the excessive retraction of the transversalis muscle beneath the internal oblique. In the operation here recommended the muscle cutting is reduced, and much of the wound in the rib bed is repaired by fibrous tissue. The diaphragm and the posterior and anterior periostea are sutured as one layer; healing is sound and no postoperative herniæ have occurred.

INDICATIONS

This incision should be used always, except when the middle or lower parts of the ureter are to be exposed.

Latterly the incision has been used in the removal of tuberculous kidneys. After the vascular pedicle has been divided, the ureter is stripped as far down as possible. The kidney is delivered and allowed to hang outside the wound, attached only by its ureter, while the wound is closed around it. The lower end of the ureter is then divided extraperitoneally through a midline infra-umbilical incision, and the kidney and ureter are withdrawn from the upper wound.

A large kidney mass is no contra-indication since the incision can be prolonged in the same line, even to the lateral border of the rectus sheath.

This operative approach has been in constant use on the surgical unit of St. Mary's Hospital for the past three years; and the improved exposure, ease of performance, and freedom from complicati [illegible] established its superiority over the other app [illegible]

Preliminary Communication

ANTIDIURETIC FACTOR IN THE U[illegible] PATIENTS WITH NUTRITIONAL [illegible]

THE pathogenesis of nutritional œde[illegible] still a[illegible] elucidation. It is, however, becoming increasingly [illegible] that this condition cannot be satisfactorily explained [illegible] the basis of Starling's classical concept of œdema formation. The hypothesis that the œde[illegible] is the re[illegible] decreased colloidal osmotic-pressure, consequent on [illegible] in the serum-albumin level, has been contradicted [illegible] several observations.[1–8] Youmans, Wells, et al.[2] emphasised the factor of tissue-pressure, but their calculations as to the magnitude of this pressure have been rejected.[illegible] It seems probable, therefore, that in the development [illegible] nutritional œdema factors other than those considered in Starling's hypothesis may be concerned.

In the present investigation it has been shown th[illegible] the urine of patients with nutritional œdema contain[illegible] antidiuretic substance which promotes water-rete[illegible]

CLINICAL MATERIAL

Twelve patients with nutritional œdema were inve[illegible] gated. Nine of these were destitutes, and the other thr[illegible] belonged to the poorest section of the community. A[illegible] were men between the ages of 25 and 50 years. In [illegible] cases a detailed dietetic history was natur[illegible] obtainable, but it was obvious that all the pa[illegible] subsisted on grossly inadequate diets for several [illegible] before they developed symptoms.

All the subjects suffered from obvious œdema, wh[illegible] pitted on pressure. The œdema was maximal in t[illegible] dependent parts; and in all cases the feet, ankles, and legs, and the hands and forearms were swollen. In the severe cases the œdema was more extensive, involving even the face. All non-nutritional causes of œdema, were including cardiovascular and renal conditions, were carefully excluded. The urine was free from albu[illegible] and granular casts. Clinical signs of wet beriberi were sought and were absent. In three typical cases lar[illegible] doses of *thiamine* given parenterally did not relieve the œdema; and in three other cases screening reveal[illegible] that the heart-shadow was either normal or smaller th[illegible] normal. Contrary to the observation of some worke[illegible] who reported polyuria in cases of nutritional œdema,[illegible] all cases here showed pronounced oliguria, the 24 h[illegible] urinary output in several cases being less than 750 [illegible] even though fluid-intake was not restricted.

EXPERIMENTAL PROCEDURE

Collection, concentration, and dialysis of urine.—The p[illegible] cedure adopted here was generally similar to that employ[illegible] by Ralli et al.[11] The urine from each patient was colle[illegible] under toluene for exactly 24 hours; care was taken to [illegible] that all the urine passed during this period was colle[illegible] ts mid-portion, was partially necrotic with a thick erent fibrinous membrane. It was subsequently ıd that the girl had been in the habit of sucking hthalene moth-balls. The case was one of true ;alocytic anæmia, resulting from deficiency of ıopoietic principle, due to chronic naphthalene ɔrption.

mears from effusions.—Dr. A. I. Spriggs (Oxford) :ribed the technique of thin, quick-drying smears ı pleural or peritoneal effusions. Mucus secretion been demonstrated in malignant cells of carcino- ous ascites by staining with the periodic acid (Schiff) ınique; of 30 malignant effusions, 20 contained ıgnisable malignant cells—this from a total of 255 ls examined.

inc-sulphate and thymol tests.—Prof. N. F. Maclagan Miss Barbara Lunnon gave an account of their ılts with the zinc-sulphate turbidity test, which been correlated with the serum-globulin level and ı other flocculation tests in a series of 100 cases re clinically the diagnosis was reasonably certain. y found a less close correlation with serum-globulin ı that described by Kunkel, but a very close correla- with the serum colloidal-gold test. The zinc- ›hate test was roughly correlated with the thymol but it was more likely to give positive results ɔn-hepatic conditions. The thymol test appeared more sensitive in acute hepatitis and gave occasional positive results in cases of lipæmia. While the sulphate and thymol tests were frequently in ement, useful information was sometimes obtained by one of these tests. Thus for diagnostic purposes best results would be obtained by combining the tests.

lloidal-gold test.—Dr. M. A. Bundock and Dr. J. N. ɪɴɢs compared three methods of performing the ;e colloidal-gold test on cerebrospinal fluid (C.S.F.) arious diseases, with special reference to neuro- ilis. The techniques used were: (*a*) the standard te gold method with saline dilutions of C.S.F.; Iaclagan's six-tube method with buffered dilutions S.F.; and (*c*) Lange's method of 1939, in which gum ti is used to stop the reaction of a citrate gold with ered dilutions of C.S.F., and in which specially pre- d standards are used for colour-matching. Reason- good agreement between all three methods was onstrated in normal fluids and in those fluids showing minimal chemical abnormalities. Method (*a*) was vn to give a few midzone curves but these gave rise o difficulty in interpretation when considered with other findings. Method (*a*) was shown to parallel clinical findings in general paralysis and tabes er than method (*c*), and both methods (*a*) and (*c*) er than method (*b*). Method (*c*) was technically ıer difficult, and although useful for a laboratory ling with many C.S.F.s, it was not recommended for tine use in an ordinary clinical laboratory. Method (*a*) ıe standard technique—which gave most help to the ician and was reasonably accurate and relatively ple to perform, was recommended.

aper-partition chromatography.—Dr. C. Dent :ribed the technique and scope of paper-partition ɔmatography. Amino-acids could be demonstrated this technique and provisional identification made n the position they had taken along the strip. More ırate identification could be obtained if large squares in. by 22 in.) of filter-paper were used, two solvents ıg successively soaked along the paper at right- les to each other. He then described a rapid "mass- duction" method, using smaller squares, which ıld be more suitable for use in pathological labora- y practice. He also described the technique used him for the study of metabolism of radioactive terials; the presence of these on the paper chromato- ms could be revealed by pressing the paper against X-ray plate. Dr. Dent remarked that many other ɔstances, such as the steroids, would soon come within scope of the method; it was only a matter of time ore most laboratories would find it necessary to use per chromatography. Dr. Dent went on to discuss investigation of patients with Fanconi syndrome. four cases fully investigated there was severe aminoaciduria with normal amino-acid pattern in the blood, suggesting a low renal threshold for amino-acids. In these patients the blood-urea was normal and the inorganic phosphorus low—the opposite of findings in renal rickets. He had also studied seven cases of cystinuria by paper chromatography; and he had found, contrary to general opinion, no evidence that this was anything more than "renal cystinuria."

Adrenal cortical function.—Dr. F. T. G. Prunty discussed laboratory aids in the assessment of adrenal cortical function. The steroids encountered in the body as a result of adrenal cortical activity could be classified, partly on a chemical and partly on a functional basis, into three groups: (1) 11-oxygenated, (2) deoxycortone-like C_{21}, and (3) C_{19} steroids. Assessment of endogenous levels of these steroids depended on measuring secondary metabolic alterations and tissue responses in the body, or else on measuring urinary excretory products. These methods could be used under "resting conditions" for evaluating the spontaneous activity of the cortex. By stimulating the system with adrenaline or A.C.T.H., the capacity of the adrenal and of the pituitary to respond could be evaluated. This was particularly valuable in differentiating primary from secondary adrenal cortical failure, and in studying the capacity of the adrenal to respond to continued stimulation by A.C.T.H.—as, for instance, in recent problems connected with the therapeutic use of A.C.T.H. in collagen diseases. The influence of A.C.T.H. on the normal individual in lowering the blood lymphocytes and eosinophils was maximal four hours after the injection; the rise observed in polymorphonuclears was thought to be a less specific effect. The effect on eosinophils could be reproduced in patients with Addison's disease and normal individuals with 11, 17-hydroxycorticosterone.

Hypertension.—Prof. Dorothy Russell demonstrated in benign hypertension the arteriolar changes, which were non-fibrinoid, and the concentric fatty changes, which could be demonstrated in the arterioles by frozen-section techniques. She showed, in malignant hypertension, the typical medial hypertrophy, the reduplication of elastic tissue (elastosis), and the severe fibrinoid changes, and suggested that these changes could be very well seen in other organs such as the pancreas and the pons. She described the explosive necrotising arteritis, and the escape of fibrinoid material into the perivascular spaces and the resulting endarteritis fibrosa which is typical of malignant hypertension. Many cases were of mixed ætiology, malignant hypertension being superimposed on the benign form.

Embolism due to amniotic fluid.—Dr. C. W. Taylor (Birmingham) demonstrated the findings in a case of fatal maternal embolism due to amniotic fluid. It was important to examine the lungs of patients dying apparently from obstetric shock during, or soon after, delivery. The emboli were only seen on microscopy, and consisted of plugs of epithelial squames similar to those seen in the alveoli of infants who have attempted to breathe in utero.

A discussion on the ætiology of malignant hypertension was opened by Prof. G. W. Pickering. Dr. N. H. Ashton reviewed new methods for research and routine examination of the eye. Dr. K. S. Thompson (Birmingham) spoke on "adamantinoma," or squamous-cell carcinoma of long bones. Dr. G. R. Osborn (Derby) described his experience of the *Papanicolaou* method of cytodiagnosis as applied to the female genital tract. The last session was occupied by a symposium on the reconstruction of human remains, in which the speakers were Prof. J. D. Boyd, Dr. C. Keith Simpson, Dr. R. D. Teare, Dr. F. D. M. Hocking (Truro), and Dr. D. E. Price (Leeds).

". . . in London, the bare cost of living for a married manual worker, on a reasonable nutritional diet, lies between £6 5*s*. and £6 10*s*. a week—quite apart from such things as hire purchase commitments—and . . . for a 'white-collar' worker, even if he be favourably placed in respect to rent, the net income required to maintain his sort of life at the minimum lies between £9 and £11. . . ."—Aylmer Vallance, *New Statesman and Nation*, Feb. 11, 1950.

There was no reason to suppose that this factor operated in the cases reported here.

It is significant that the cases here suffered from oliguria, the diminution in urinary output paralleling the severity of the œdema. The present investigation suggests that this low urine-volume may be the cause rather than the result of water-retention.

SUMMARY

An antidiuretic substance has been found in the concentrated, non-dialysable fraction of urine from cases of nutritional œdema.

I am grateful to Prof. A. S. Ramachandra Iyer, of Madras Medical College; the Principal, of the college; and the physicians of the Government General Hospital, Madras, for the facilities extended to me. I also thank Dr. V. N. Patwardhan, director of the Nutrition Research Laboratories, Coonoor, for his helpful interest in the work.

FOLD IN THE POSTERIOR VAGINAL WALL

IF two fingers are passed along the posterior vaginal wall, a loose transverse fold is sometimes found above the level of the upper edge of the levator muscles. At the level of this fold the rectovaginal is relatively patulous. The slackness of the vaginal in the fold is taken up when the bowel becomes distended with fæces; and the purpose of the fold may be to the vagina to stretch when the rectum becomes distended. The fold may not be present in multiparæ who have experienced extensive perineal lacerations, and it is invariably present in nulliparæ.

The fold does not seem to be mentioned in any of the medical literature with which we are acquainted. may have functions other than the one already mentioned and it seems strange that the fold is not invariably present in nulliparæ.

Medical Societies

ASSOCIATION OF CLINICAL PATHOLOGISTS

THIS association's 43rd scientific meeting was held at Brighton, under the presidency of Dr. NORAH SCHUSTER, on Jan. 26–28.

Penicillin in exudates.—Dr. J. UNGAR (Greenford) compared the levels of penicillin in blood and inflamed tissues, and showed that after a single intramuscular injection penicillin could be detected in the tissue exudates for considerably longer periods than in blood. He regarded this selective accumulation of penicillin in exudates as one of the most important factors responsible for the therapeutic effects of single massive doses.

Antibiotics.—Prof. ROBERT CRUICKSHANK made a strong plea against the use of multiple "blunderbuss" therapy, and suggested that intelligent coöperation with the bacteriologist would nearly always show which drug should be used. With resistant staphylococci, the resistance might be only relative; larger doses would still be effective in many such infections. With chloramphenicol the laboratory tests were easy; but 'Aureomycin' presented difficulties as it was unstable, and no satisfactory method was yet available for routine work. In dealing with typhoid, drugs should be continued for at least fourteen days; the bacteria were inaccessible in the bile and their excretion could be maintained despite therapy. He spoke of the complications of vitamin-B deficiency following chloramphenicol therapy.

Toxoplasmosis.—Dr. A. MACDONALD (Liverpool) spoke of the value of the various laboratory procedures used in the diagnosis of toxoplasmosis, and said that the complement-fixation test was probably the most convenient for the ordinary laboratory. Sabin and Feldman's test for cytoplasm-modifying antibody was extremely sensitive but required the use of living parasites. The soluble egg antigen used for complement-fixation tests maintained its potency if kept frozen. In Liverpool they had found good general agreement between the results of different types of test. Examination of maternal and cord blood showed that transference of maternal antibody occurred, so in very young infants serological tests had to be interpreted with caution. While infection with toxoplasma was not so rare as had been thought, it was as well to remember that toxoplasmosis was only one of a number of conditions which could produce very similar clinical manifestations.

Pulmonary tuberculosis as a necropsy hazard.—Dr. STEWART SMITH (Exeter) drew attention to pulmonary tuberculosis as a necropsy hazard. There was much evidence that fresh post-mortem tissue was a ready source of tubercle bacilli for post-mortem attendants, medical students, and others. Prophylaxis should include routine Mantoux tests and periodic X-ray examinations, careful consideration of the hygiene of the post-mortem room, and limitation of the number of necropsies done on cases of proven tuberculosis. He suggested that this should be scheduled as an industrial disease. Prof. R. J. V. PULVERTAFT proposed that in addition ultraviolet light should be used for bactericidal effect, and that the air should be [illegible] Dr. A. H. T. ROBB-SMITH said that adequate ventilation, free use of 'Lysol,' adequate sterilisers, and the wearing of masks would also help to limit the [illegible]

Dextran and anti-Rh antibodies.—Dr. A. RICHARDSON JONES (Portsmouth) described his experiments with dextran as a potentiator of incomplete anti-Rh antibodies. This substance possessed a potentiating action but the commercial substance was unsatisfactory for routine laboratory use because it caused gross rouleaux formation of the test cells and it failed to potentiate all incomplete antibodies. This failure was thought to be related to dextran's polydisperse constitution. The potentiating property was due to a relatively narrow range of molecular size, and furthermore it seemed as though certain other molecules had an inhibitory effect. In an attempt to relate potentiating power to molecular size, Dr. Richardson Jones had undertaken the acetone fractionation of commercial dextran; and so far he had succeeded in producing a potent fraction which potentiated all incomplete antisera with which it had been tested. It caused no rouleaux and gave antibody titres closely comparable with those obtained by albumin potentiation. He felt that this fraction offered a substitute for bovine albumin in cross-matching for transfusion and in testing the serum of pregnant women for anti-Rh antibodies. Particular advantages of dextran were its chemical stability and its cheapness.

Monocytic leukæmia.—Dr. C. D. ANDERSON and Dr. G. B. ROBERTS (Glasgow) reported a case of monocytic leukæmia in a young girl with a typical leukæmic blood picture and a highly cellular leukæmic marrow. After treatment with urethane she developed staphylococcal pneumonia, which was successfully treated with penicillin; after this no abnormal cells were found in the peripheral blood and the total marrow picture returned to normal. Some weeks later numerous chloromas appeared and the patient died. At necropsy there was no evidence of diffuse leukæmia, but numerous chloromas were found.

Naphthalene poisoning.—Prof. D. F. CAPPELL and Dr. J. R. ANDERSON (Glasgow) presented a case of megalocytic anæmia with hyperplastic marrow of megaloblastic type in a girl of 17, admitted to hospital critically ill with profound anæmia. The early findings were indistinguishable from pernicious anæmia, but the gastric contents contained free hydrochloric acid. Despite treatment the patient died, and at necropsy the ileum showed a severe inflammatory lesion which

The Forgotten Swab

[HE tragic story of the surgical swab is told over 1 over again. year in and year out. before judge 1 coroner. It seems incredible that any highly .ined theatre team should not have a foolproof stem for such elementary book-keeping as "swabs nded out, swabs handed back." and it is high time at this part of the surgical house was put in order. be discarded first is the attitude of "it can't ppen to us." Any surgeon who has worn his gloves ig enough, and has operated in nursing-home eatres with an inferior staff or equipment, can recall her a personal accident of this sort or the removal of abs left by others. (This indeed was the comment a surgeon at an inquest last month.[1]) Though the dominal cavity is the largest. it is not the only nger area: swabs have been overlooked recently ring removal of a lumbar disc, and also in a hip .hroplasty, and vaginal packs are continually being gotten.

The surgeon always feels that he ought not to be ddled with responsibility for checking swabs: he s not the time to count every swab handed by the .ter before or during the operation, and thus he has rely on her word or nod. In Massachusetts. U.S.A.. rgeons are in fact absolved by law from all duty of ersight: but in the rest of the U.S.A. and in this untry responsibility for accidents is assessed by e courts according to the particular circumstances. roadly speaking, judges have held that the surgeon not to be blamed for leaving a swab in the abdominal .vity provided he has organised an efficient system r swab-counting and at the end of the operation is asked the nurse whether the count is complete. f he relies on the nurse to tell him, without being .ked, his defence is less satisfactory.) Provided he ıs made reasonable arrangements and has taken ıe precaution of asking, the court will probably hold m blameless, and the responsibility will shift to ıe nurse. In bringing an action for negligence. ıe patient's solicitor usually casts his net wide. cusing the surgeon, the nurse, and the hospital. the surgeon alone is found negligent. the hospital exonerated; for a hospital is not responsible for ıe professional acts of the duly qualified doctors ho work in it. If, on the other hand, the nurse is ound negligent, the hospital may have to pay, because he is an employee of the hospital, not professionally utonomous in the same way as a doctor. In an accusation of negligence the onus of proving that the surgeon (or other person concerned) has not exercised reasonable care and skill always rests on the plaintiff, unless the court takes the view that *res ipsa loquitur* (the facts speak for themselves), in which case the defendant has to prove that he *did* exercise reasonable care and skill. Where the object left in the abdominal cavity is an instrument rather than a swab, the court is more likely to say that it is for the surgeon to explain why he should not be deemed negligent.

Are there any measures which would make for greater safety? There certainly seem to be a number. Every theatre needs a swab-horse—that is, a numbered rack; to spread swabs on the theatre floor is a dirty habit. The swabs handed to the surgeon should be entered on a blackboard, for all to see. Often the anæsthetist's swabs are a source of confusion in the final count, and it is good practice to provide him with dyed swabs (usually they are green). Time and again the missing swab for which the surgeon. usually in irate mood. turns out the entire abdomen. is found to have been removed with the specimen: no swab should ever be taken out of the theatre during the operation. The layman, seeing a "large" swab for the first time in the coroner's court, will think that only the grossest carelessness could overlook it; but within the coils of the bowel, or tucked into Morison's pouch or the pelvis, it can form an astonishingly small lump. Miscounting of swabs in the original drum packing is another occasional cause of error. It is easy to say that no large swab could be left behind if the surgeon would spend a moment clipping a hæmostat to the attached tape-end; and this is of course the usual practice. But in the fury of a sudden vicious hæmorrhage or other emergency. the surgeon will often grasp the nearest forceps and allow the swab its head to roam. An excellent means of ensuring correct packing and checking is for large swabs to have numbered metal discs attached (say 1–10): on return to the checking nurse these disced swabs are placed on the appropriate numbered hooks. The metal discs are also valuable for X-ray purposes when there is any question of a swab having been left behind. Some surgeons limit themselves to a fixed number of swabs and count these themselves; but this habit distresses some theatre-sisters, and few surgeons care to be thus restricted. Others hold that the employment of gauze rolls is safer, but there is still the danger of cutting these and confusing the count; and each cut should be recorded numerically on the board. Once the abdominal cavity has been opened. no small swab has any place on the operating field; little swabs. like little boys, must not go near deep holes, and they should be presented to the surgeon only on holders. In some fields, however—for example, in cervical sympathectomy—a small-swab packet may have to be inserted for the control of sudden hæmorrhage. To check this—and indeed to check all swabs packed into any cavity—the floor nurse may assist by hanging large red discs on the horse, and removing them as the swabs come out.

Even with these aids, the surgeon must still keep his surgical reflexes in trim; as he starts to close the cavity out must come the words, "Are all swabs correct"? One surgeon, we hear, has had a red light attached to the swab-horse. and this stays on as a

Reviews of Books

Applied Medicine

G. E. BEAUMONT, M.A., D.M., F.R.C.P., physician to the Middlesex and Brompton Hospitals. London: J. & A. Churchill. 1950. Pp. 540. 30*s.*

IN this interesting and exciting book Dr. Beaumont uses a new technique for teaching medicine. The systematic description of disease gives way to the discussion of actual cases. Some are presented with fully documented histories; others are met at the bedside, with the questions and answers of a teaching round. As the findings are gradually revealed, the problems of diagnosis and treatment are tackled, with discussion of the interpretation of physical signs and of the significance of the actual investigations that have been used. The reader can thus follow the "working out" of the case and can also appreciate the problems that await the practising physician. All varieties of cases are presented; some common, others rare; some humorous, others tragic; some easy to diagnose, others very difficult. In a delightful manner, Dr. Beaumont manages to portray the fascination and excitement of medical practice. This is not applied, but living, medicine. The amount of information this volume contains is enormous, but this is no reference book—rather one to be kept by the bedside and read and reread. No student, practitioner, or even consultant could read it without gain and enjoyment. Many teachers of medicine will wish that they could have written such a book, but how few could have done so!

Sight, Light, and Efficiency

H. C. WESTON, director of group for research in occupational optics; secretary of the visions committee, Medical Research Council. London: H. K. Lewis. 1949. Pp. 308. 42*s.*

Mr. Weston is a physicist who has made a study of vision, especially as it concerns lighting and industrial needs, and his book is a useful exposition of the problem of eye fatigue in industry and how it may be overcome. Since it is intended for the industrialist, the opening chapter gives the elementary anatomy of the eye—accurate except that it confuses the posterior and the vitreous chamber. Chapters on the physiology of vision follow, and on the cause and symptoms of "eyestrain," better called "eye fatigue." (We do not speak of its counterparts in other organs as leg strain or brain strain, and so forth; and it is surely better to avoid a word which carries an idea of lasting damage.) In the chapters on lighting Mr. Weston is on his home ground and his exposition is excellent, but the same cannot be said about his section on eye disease produced by injury. It may be academically correct to say that the cornea is covered with conjunctiva, but this becomes confusing when ulcers and foreign bodies in the cornea have to be described as lying in the conjunctiva. Nor is it wise for a physicist to hazard too many opinions on medical prognosis, and not all his conclusions in this section can be accepted. Nevertheless, the book, taken as a whole, is a useful exposition of the subject and shows employers how, by better lighting in factories, they may increase efficiency and therefore production.

Normal Values in Clinical Medicine

F. WILLIAM SUNDERMAN, M.D., PH.D., professor of experimental medicine and clinical pathology, University of Texas postgraduate school of medicine; FREDERICK BOERNER, M.D., late associate professor of clinical bacteriology, graduate school of medicine, University of Pennsylvania. London and Philadelphia: W. B. Saunders. 1949. Pp. 845. 70*s.*

THIS book fills a gap that doctors often notice. The multiplicity of investigations nowadays demands frequent review of the "normal" standards on which conclusions must be based. It is indeed surprising how often the normal not only is difficult to discover in books but is in fact not accurately known. Dr. Sunderman and the late Dr. Boerner have collected data on a very large number of normal findings in almost all branches of clinical investigation. Their book is divided into sections according to the body systems, with a final section of miscellaneous information including food values, doses, and actuarial tables. The largest section, as would be expected, is that covering normal values in blood, extracellular fluids and lymph, though that on the cellular elements of the blood is little less important. The diversity of subjects is enormous, ranging from scalp hair counts in blond and black-haired subjects to normals in electrocardiography, œstrogen determinations, and anatomy.

The value of this book to those who have to assess findings in the sick is obvious. It also emphasises the importance of having accurate figures for the normal range before speaking of the abnormal. Both doctors and students will be grateful for the ready help it can give them.

Bronchologie

Technique endoscopique et pathologie trachéo-bronchique. ANDRÉ SOULAS; P. MONNIER-KUHN. Paris: [illegible] 1949. Pp. 653. Fr. 4000.

IN this massive work the authors have set out to describe in detail the ranges and uses of bronchoscopy. In this they are helped by admirable production (though the cover is of paper) and more than 300 illustrations together with more than 20 excellent colour plates illustrating bronchoscopic appearances and histology. In describing the technique perhaps too much detail is given, since individual variations in instrumentation and anæsthetic are almost too numerous to be mentioned. On some minor points the opinions presented are open to dispute—e.g., the risks of general anæsthesia in bronchoscopy and the condemnation of the cricothyroid route in bronchography. The description of bronchial anatomy and segmental distribution is a full one, with which there will be agreement in general though the terminology used will add further confusion to a nomenclature already well confused. The removal of all types of foreign body through the bronchoscope is described at length; but little favourable is said about the open operation, which also has a place. Possibly the best descriptive chapters are concerned with tracheobronchial tuberculosis and growths. The authors hold the balance fairly between endoscopy and more major surgery, as they do also in dealing with lung abscess.

The book has just stopped short of becoming a comprehensive volume on chest medicine and surgery, for it successfully follows every path that the bronchi [illegible] for exploring a very wide field.

Stedman's Medical Dictionary (17th ed. London: *Baillière, Tindall, and Cox. 1950. Pp. 1361.* 65*s.*)—Dr. N. [illegible] Taylor and Mr. A. E. Taylor have revised this good dictionary, adding new words and diagrammatic chemical formulæ, and cutting out dead wood even to the extent of dropping the word "Practical" from the title. No new trade names have been added, and most of those in the previous edition have been excluded. A new feature is the inclusion of [illegible] biographical sketches. The net result is an addition of seventy pages.

Bridges' Dietetics for the Clinician (5th ed. London: Henry Kimpton. 1949. Pp. 898. 60*s.*).—Americans have taken dietetics to their hearts. This is the third major work on dietetics, published in the United States, which has reached its fifth edition in the last year or two. Edited by Dr. Har[illegible] Johnson, it differs from the other two in that *it is a* symposium, and it has all the advantages and disadvantages of that mode of treatment. It is noteworthy that [illegible] surgeons are interested in the *preoperative* and postoperative diets of their patients—a welcome innovation. The book can be recommended to all concerned with the diet of the sick; it is a mine of *information*. One amusing fact is that the *administration of large* doses (50–100 mg. twice daily) of thiamine makes one distasteful to fleas and mosquitoes; another that poisoning from arsenic, derived from fruit sprays, is not at all uncommon, and that the only foods free from arsenic in New York City are milk and bananas. The section on *the classification* and structure of foods, however, is surprisingly out of date for an American publication. It was not, of course, to be expected that vitamin B_{12} would be noted, but on the subject of phytates the book is ten years behind the times. This may have small practical importance in the U.S.A., but it may matter considerably in [illegible] where the calcium intake is *marginal or too low.*

sists on a thorough grounding in the general sciences fore and during the period of technological training the university laboratories and industrial workops. But the effort to provide true education can arcely be maintained if the Government yield to ose who urge that the universities should expand eir departments rapidly in order to accommodate ainees in technology. Already, the University rants Committee notes,[4] the number of students the departments of applied science has risen from 288 in 1938–39 to 10,916 at the present time. Further, ere are other means by which technological struction can be given. Already there are five ational training colleges—for aeronautics, instruent-making, foundry work, heating and ventilation, nd rubber technology—and compared with the ifficulties of enlarging our older universities without arming them the problem of providing more State echnological colleges seems almost simple. Meanhile, much closer coöperation could be achieved etween the universities and the technical colleges, nd collaboration would be made easier if the senior niversity staff were relieved of some of the burden of outine teaching and administration, and if research nits in the technical colleges of our university towns ere more generously equipped. There is a happy recedent for close liaison in Manchester, where the echnical college constitutes the faculty of technology n the university, and in Glasgow, where staff and tudents in the departments of architecture and of harmacy move freely between university and echnical college.

Yet another approach to technological development s revealed in the publication of a *Handbook of Departnents in the University of Edinburgh related to Industry.*[5] The purpose of this booklet is explained in the preface y Mr. E. P. Hudson, convener of the university's ndustrial liaison committee :

> "There is scope for making better known in industrial circles the names, achievements and particular interests of the many university men and women whose work in teaching and research will, we can be sure, contribute in full measure to the advancement of knowledge and thus have an influence on current and future industrial techniques and practices."

Sir Edward Appleton, F.R.S., principal of the university, in a foreword, urges that those who conduct scientific research "must be free to seek understanding of natural phenomena without having constantly to justify their efforts by utilitarian results." But he goes on : "If a university is to remain a real force in the world it cannot remain aloof from the practical problems which face mankind ; and, in so far as such problems are scientific and industrial, our university workers can often make suggestions for their solution. They can also, with immediate advantage both to Science and to Industry, conduct what may be called objective fundamental research of a basic character." This example of the national genius for compromise, coming from a distinguished scientist, deserves attention from all who guide the destiny of this country or who decide the pattern of our educational system.

Wound Infection in the Factory

Wound infection has long been a major hazard of wars. The experience in 1939–45 confirmed earlier impressions that much of this infection occurs after the patient has reached hospital and is largely due to the accessibility of open wounds to pyogenic bacteria, particularly *Strep. pyogenes*, derived from already infected cases in the wards. The modes of spread and means of control of this type of hospital infection were extensively studied in the late war ; but the no-touch technique, dust control, and other measures advocated achieved little compared with the radical change in the whole picture which followed the general introduction of penicillin.

In peace-time, infection of wounds attracts little attention in hospital practice, though the outpatient surgeon has to deal with the disabilities left as its aftermath. In industry, however, infected injuries are a significant cause of sickness absenteeism leading to the loss of about a million working days every year. In one light-engineering factory, 27% of the injuries that kept men away from work for more than three days were infected wounds, though only 1–2% of the trivial wounds which 6–8% of the employees sustained each day became septic. Most of the septic wounds seen in the hospital casualty department have followed injuries that at first seemed so trivial as not to call for any immediate treatment. These data emerge from an investigation of wound infection by a Medical Research Council unit established in 1942 under the direction of Dr. R. E. O. Williams and Dr. A. A. Miles, at the Birmingham Accident Hospital, where large numbers of industrial wounds can be studied under conditions likely to yield reliable information in the shortest possible time. The report[1] on the first three years' work adds much to our knowledge of the bacteriology of infected wounds, particularly in regard to the frequency, sources, and control of infections with the two commonest pyogenic cocci, *Staph. aureus* and *Strep. pyogenes*. The greater part of the report deals with the results of a study of 2300 small wounds classified in three groups—minor lacerations of the hands and forearms; compound fractures of terminal phalanges of fingers, and small skin wounds treated in factory surgeries—and observed and treated within 6–8 hours of the injury. It was first determined that *Staph. aureus* was present, often in pure culture, in 80–90% and *Strep. pyogenes* in 20–25% of septic wounds. These wounds might have been infected at the time of injury or later, and the infecting organism could have been derived from the patient himself (self-infection) or from an outside source (cross-infection). Earlier findings had indicated that hæmolytic streptococci were usually "added" to the lesion from an exogenous source, but with staphylococci the source seemed most often to be the patient himself. Thus coagulase-positive staphylococci were found in the noses of about half of 1000 normal adults, while the proportion who were carrying the organism on their skin varied from 20 to 50%, according to the area of skin sampled and the cultural methods used. Skin carriage was related to, and dependent on, nose carriage, and it has since been useful reminder; he can then end the operation with the request "red light off." In a few hospitals the theatre-sister keeps a book in which the names of the swab-checking nurses are entered. This does not imply legal responsibility, but it impresses them with the importance of their duties.

[1] Infection and Sepsis in Industrial Wounds of the Hands. *Spec Rep. Ser. med. Res. Coun., Lond.* no. 266. H.M. Stationery Office, 1949.

That an instrument such as a forceps should be left within the abdomen seems to the layman almost beyond belief; but with profuse bleeding from a ruptured ectopic gestation this mishap is easily imaginable. The forceps left behind in a case reported a week or two ago[2] was a small one; and small forceps should never be used in a pelvic operation. It must be admitted that in many hospitals the instrument-count receives scant attention: often, because of the shortage of instruments, particularly hæmostats, the sister hands over some of them for re-sterilisation before the operation is finished. Moreover, few hospitals keep a list of the instruments set out in each particular operation. These are hazards to which the attention of the theatre-sister might be drawn.

The mood of the theatre is usually set by the surgeon. If he is casual in his discipline and wayward in his own precautions, then these avoidable tragedies will continue and he must bear part at least of the responsibility. Nobody knows better than the surgeon that "he is most safe from danger who, even when safe, is on his guard"—*caret periculo, qui etiam tutus cavet*. Perhaps this is a slogan worth putting on the swab-horse. Another is "It may happen to me!"

The Universities and Industry

BY and large our universities have little to fear from the most searching scrutiny, and there is no lack of spokesmen to justify the academic way of life. Sir JOHN ANDERSON[3] lately referred to the functions of a university as "Clinging tenaciously to what is vital—the conservation of knowledge, its interpretation, a vigorous and sustained effort to enlarge its boundaries, and the training of those who will carry aloft the torch of learning as generation succeeds generation." Thus the universities should above all be the guardians of the spirit of man, the spirit that lived in the heart of GOETHE, PASCAL, and SHAKESPEARE. This duty implies that whatever other concessions they make to expediency they must defend the ideals and standards of personal and intellectual freedom which belong to our English heritage. But MILTON spurned "the fugitive and cloistered virtue, unexercised and unbreathed, that never sallies out and sees her adversary"; and neither high principle nor the pursuit of knowledge for its own sake can justify a policy of reaction and of indifference to the unprecedented perils which now beset mankind. The accepted distinction between thinkers and dreamers on the one hand and men of action on the other does not imply that they are necessarily antagonists. In a vital nation there must be a heterogeneous pattern of interests and behaviour. Science, no less than philosophy and religion, has its eternal verities, and, however spectacular may be the superstructure built on these foundations, to neglect them is to invite chaos.

Pure and applied science owe an enormous debt t one another. But there will always be those who te the basic sciences without the slightest regard f utility, and rightly so. Is anything to be gained (lost) by their living cheek by jowl with others wh pursue applied science as it concerns the industrial the shopkeeper, and the housewife? This questi raises important issues, even apart from geograph or architectural considerations. Boys and girls school are inclined to regard the universities as insti tions which provide degrees and diplomas entitling th holders to "good jobs." Furthermore, recent correspondence in the *Times* has revealed a weight of opinion in favour of placing on the universities resp sibility for technological training. Admittedly, th can be no doubt about the need for developing o technological resources: the Barlow report, wh emphasised the urgent need for more technicians a scientists, has received corroboration from many o our most eminent directors of scientific resea "We need first-rate technologists most desperately i order to regain our prosperity," said Sir LAWRE BRAGG, F.R.S., at the Annual Conference of th Universities of Great Britain and Ireland; and Lo CHERWELL wrote in the *Times* of Dec. 9: "Un people in Britain can be . . . brought to appreciate th value of technical education in the broadest se there is little hope of our recapturing the indus leadership on which our primacy in the nineteenth century was founded." Nobody will deny th prompt and vigorous action is required to these alarming deficiencies, and it is nat industrialists and others should look first to th universities for the development of high-grade techno-logy. But there are serious objections to any pl which might eventually convert our universities in gigantic technical institutions of the types that alread exist in the U.S.A. and on the Continent. It is o thing to take a university course in the humaniti or in general science as a preliminary to specialisat in technology; it is quite another to go to th university for a highly specialised technological cour as a preparation for a routine job in industry or in scientific research department. Such a plan wo inevitably swamp our universities with students o technology and would eventually relegate the ancie faculties to some dim annexe of the university facto

What then is the true function of a university the report of the University Grants Committee 1935–47 (p. 60) we read:

> ". . . a University would in our view fail of essential purpose if it did not, by some means or oth contrive to combine its vocational functions with t provision of a broad humanistic culture and a suit tough intellectual discipline. Nearly all the Gov ment Reports . . . have emphasised the point that special kinds of professional or technological tra with which they are concerned should include as t basis the study of broad underlying principles this should be the distinguishing mark of a univ

In the training of a doctor this objective has bee achieved to some extent—though by no mea adequately. The study of biology, chemistry, phy anatomy, physiology, biochemistry, and pharmaco-logy should, in theory, provide ample opportunity fo instilling general principles before strictly vocation training in the practice of medicine begins in the thir or fourth year. Similarly the faculty of engineerin ure that it can be properly done only by someone h medical training, his remuneration should be nparable to that of any colleague of similar skill and niority elsewhere in the medical service? In our xiety to see that the clinician did not find himself bservient to the medical administrator, may we not ve allowed the pendulum to swing too far, with the ult that senior administrative posts in the hospital d public-health service, many of them filled by men considerable clinical experience, are now the least well id of all? It is possible that current negotiations may nedy this; though the refusal of the Treasury last ek to agree to the salary increases proposed for vernment medical officers does not encourage optimism. Clearly, until this happens, any decision to pay the est physician partly as a clinician and partly as an ministrator must reduce the attractiveness of the ecialty and make it harder to recruit to the service e men of foresight and ability needed if this foremost disabling diseases is to be brought, and kept, under ntrol.

ON WASHING THE DISHES

THERE are few of us who are not now adepts at the tchen sink; we have not even the privilege of grand- ther's butler who condescended to deal only with the ss, silverware, and cutlery, sending the greasy plates the kitchen for some lesser minion to cleanse. Today ost of us are prepared not only to wash the plates and plements from the dining-room table but to furbish pots and pans and the roasting tin as well. We have n learned the correct technique whereby glassware, er, side-plates, pudding plates, cutlery, and meat tes follow in due order lest the grease from the last-med contaminates the lustre of the first. The work is t arduous; the company of a congenial dryer makes it asant enough, though it wastes a lot of time. Never-less we have become a population at risk, for sink-rk has hazards that lurk in the sodium carbonate or her detergent which so many of us splash all too vishly into the washing-up water.

Dermatitis of the hands due to sensitisation to deter- nt solutions is one form of "housewife's dermatitis." ost dermatologists agree that this malady is now more ten seen in outpatient departments and in private actice than before the war; but they are uncertain hether the increase is more apparent than real—hether, in fact, they are seeing more cases only because any more of the population are now at risk, while the orbidity-rate really is about the same. They speak of he hazards of "green labour," which is an unflattering ethod of referring to those whose delicate skins have ot been inured by experience to the risks to which hey are exposed. The more erudite have been heard to iscuss the effect of a low-protein and low-fat diet on the efence mechanisms of the body.

Be this as it may, certain matters undoubtedly deserve ttention. The first is that all household detergents tend o remove the natural greases from the surface of the skin; and, as these are necessary for the integrity of the horny layer, frequent exposure to them—particularly f they are used in unnecessarily high concentrations—may easily make the epidermis vulnerable so that sensitisation can occur. Accordingly the concentration of detergent in the water should be minimal. As to the nature of the detergent used, it would be invidious for us to recommend one we believe to be the safest. Let each try for himself; he can soon discover which detergents leave the hands dry, uncomfortable, and chapped, and those which perform their function adequately yet with little harm. In addition a good deal may be done to protect the hands. Rubber gloves of the usual household variety are seldom satisfactory, for not only are they easily punctured, so that the solution seeps into the interior and forms a poultice, thus enhancing the wearer's risk, but the skin becomes sodden with sweat, while the breakage rate of the crockery rises. Probably it is better to keep a tube of lanolin at the sink and apply this before and after washing up; being made of mammalian sebum it helps considerably to reinforce the natural defences of the skin. Recently a barrier cream of the invisible glove type, which presumably has a sodium alginate base, has become available to the public; it has many advocates. To do its work properly, a barrier cream must be applied carefully, particularly to the vulnerable areas, the backs of the webs and the backs and sides of the fingers, before the hands are immersed. Less efficacious, but none the less satisfactory, is a suitable cold cream kept at the bedside and applied last thing at night. A good one with an old-fashioned formula is made by emulsifying beeswax (8%), spermaceti (16%), and almond oil (56%), with borax (1%) in rose water.

If, despite these precautions, dermatitis develops, it is inadvisable immediately to presume that washing up is the cause of the trouble. A list of all the hazards to which one is exposed should be made, not forgetting that the antiseptics and even the spirit used in our profession are all sensitisers. By avoiding exposure to all irritants, and by using the usual remedies such as calamine lotion during the acute stage, with zinc cream or zinc and castor-oil ointment later, the average attack of dermatitis may be mastered in about three weeks. Then comes the time to make tests. The full routine of patch-testing may be employed, but it is usually less troublesome to immerse a little finger in a warm solution of the suspected detergent for one minute: if one is sensitised, a recurrence of the eruption is likely to follow within 24 hours. Thereafter one has only to avoid that detergent, or any other which has chemical affinities with it, and all will be well; but it is worth remembering that if one's skin becomes allergic to any detergent, polyvalent sensitivities to many similar hazards may readily be acquired; and for a while it will be best to confine one's domestic activities to the less hazardous job of drying.

THE PRESENT STATUS OF AUREOMYCIN

IN the eighteen months since 'Aureomycin' was introduced by Duggar in the U.S.A. about a hundred papers on it have been published. It is unfortunate that lack of dollars is limiting supplies in this country, though the shortage at least ensures that the drug is used only in carefully planned trials or for the established indications. The American experience suggests that aureomycin will be one of the most valuable antibiotics in general medicine. Its range of activity is wider than that of any other antibiotic; it is effective against many gram-positive and gram-negative bacteria, and also against rickettsias, spirochætes, and even some viruses; it can be given by mouth; and it has been judged practically free from side-effects, the only troublesome ones reported being nausea and vomiting, sometimes with epigastric distress and a burning feeling in the rectum. However, Harris[1] reports rapidly developing mucous-membrane changes in many female patients, attributed to vitamin-B deficiency through destruction of intestinal bacteria—a complication also associated with administration of chloramphenicol. As a rule patients who cannot tolerate aureomycin by mouth experience no unpleasant effects when it is given intravenously. Owing to its bacteriostatic action on the bacteria of the gut, one peculiar effect of the drug is to produce soft and almost odourless stools. When given by mouth aureomycin is absorbed into the general circulation and is only slowly excreted: a dose of 0·5–1 g. will maintain an effective blood-level for about six hours. From the blood the drug is distributed to all the body-fluids and tissues, including the urine, cerebrospinal fluid, pleural fluid, and bile, and it also reaches the fœtus in utero via the placenta.

1. Harris, H. J. *J. Amer. med. Ass.* 1950, 142, 161.

shown that elimination of staphylococci from the nose is often followed by disappearance of the organism from the skin.[2] *Strep. pyogenes* was found in an average of 11·7% of outpatients' throats (the seasonal rate fluctuated considerably over 2½ years) and on the skin of only 0·4% (6 out of 1630). The opportunity for self-infection should therefore be much greater with staphylococci than with streptococci, and in fact it was found that whereas 20% of wounds yielded *Staph. aureus* within 6–8 hours of the accident, the proportion was 26·6–53·2% in patients who were skin carriers of the organism but only 6·9–14·8% in those who were not. The proportion of wounds contaminated with staphylococci was as high in the first hour after the injury as in each of the successive 5 hours, and the staphylococcus found in the wound was often of the same phage-type as that on the skin. There was very little likelihood of the wound being contaminated from machinery and the like. Some three-quarters of all the wounds healed without any clinical signs of infection. *Staph. aureus* was isolated from a third of these healthy-looking wounds, whereas pyogenic cocci were absent from nearly half of the wounds that looked inflamed, from a quarter of the ones classed as mildly septic, and from 5% of the grossly septic wounds. In this last group there was evidence again that 50–60% of the staphylococcal infections were derived from staphylococci present on the patient's skin at the time of injury, but this conclusion does not invalidate the recent evidence that staphylococcal cross-infection is common in hospital wards. Very few of the streptococcal infections were derived from the patient. Clinically and bacteriologically clean wounds had a mean healing-time of 16·1 days, obviously septic wounds healed in 31·5 days, and wounds which were bacteriologically but not clinically infected healed rather more slowly than the first group, partly because some of them became infected during the delayed healing.

Prevention of wound infection may be tackled in a variety of ways. Improvement in dressing technique, particularly when accompanied by improvements in the design of the dressing-station, has strikingly reduced the streptococcal infections, which are most often exogenous, and probably also reduces staphylococcal infections to some extent. Thorough cleansing of the wound with a detergent like cetrimide was found to reduce the infection-rate in the Birmingham study, and repeated applications of sulphathiazole-proflavine powder did the same, whereas a single application of penicillin powder was ineffective. The use of occlusive waterproof dressings did not prevent staphylococcal infection or accelerate healing. On the other hand, in this issue Dr. **Schilling** and his colleagues report encouraging results with the 'Nylon' dressing recommended by **Bull** and others.[3] The advantages of this over the ordinary occlusive dressing are that its permeability to water vapour prevents the skin from becoming sodden, the "window" allows healing to be watched by both patient and nurse, and infrequent changing of the dressing saves time. However, **Williams** and **Miles** have shown that wounds may be potentially infected before any dressing is applied and that only a small proportion of septic wounds receive medical attention before the sepsis develops. Prophylactic measures should include efforts to prevent the minor injuries from metallic filings and the like (swarf) now common in engineering factories, and attempts to prevent skin carriage of staphylococci in workpeople by attacking the nasal reservoir or the skin itself with a suitable antiseptic ointment.

Annotations

THE CHEST PHYSICIAN

Commenting a few weeks ago on the correspondence about control of tuberculosis, we suggested[1] that the fight against this disease should be given a larger share of medical resources than it is now getting. We said that:

> "Anyone coming to this problem with fresh eyes and an unperverted sense of proportion would certainly demand that priority for tuberculosis should be raised, that waiting-lists should be abolished at once by admitting patients to infectious-diseases and general hospitals, and that the complementary domiciliary service should be developed and used for its proper purpose—as a means of giving efficient and economical care to patients who have been made non-infective."

Such a policy clearly requires a cadre of first-class clinicians in control of the chest clinics, to ensure early diagnosis, wise care before the admission to hospital, and the best use of the domiciliary services when the patient returns home.

Before the National Health Service was introduced, the work of the tuberculosis officer, despite its importance, was generally unattractive both in status and remuneration. The transfer of the chest clinics to the regional boards and their incorporation in the hospital service raised the hope that in future this work would compete on equal terms with other branches of medicine, and this hope seemed to approach fulfilment when many of the experienced men in charge of the clinics were graded as consultants. But evidently the rejoicing was premature; for the Ministry of Health has now decided that a chest physician can be recognised and paid as a consultant only during the hours he is working for the regional hospital board: for the portion of his work concerned with prevention and aftercare he rates as an assistant to the medical officer of health, and must be paid a commensurately lower salary. This decision drew an indignant letter from Dr. Toussaint in our last issue and he is supported this week.

It is both difficult and unprofitable to draw a dividing line between the preventive and curative parts of any clinician's work: always the one merges into and supplements the other. In no specialty is this truer than in tuberculosis, where the preventive and the therapeutic sides cannot be separated. Neither is more important than the other; neither can be effective alone; each demands high clinical ability; and neither could be undertaken except by a doctor, and one well grounded in the specialty. Yet it is now suggested that for an empirically determined portion of his time the chest physician shall be paid at a cut rate. It is true that for the better conduct of his duties in prevention and aftercare he needs the cooperation of social workers, and that the Act leaves the responsibility for organising and conducting this section of the service with the local health authority. But even though the physician is one of the servants of the local authority for this moiety of his duties, he is none the less a clinician and should be regarded as such, and not as an administrative officer of lower grade.

Should we not in fact go further, and say that whenever a doctor is doing administrative work of such a nature that it can be properly done only by someone with medical training, his remuneration should be comparable to that of any colleague of similar skill and seniority elsewhere in the medical service? In our anxiety to see that the clinician did not find himself subservient to the medical administrator, may we not have allowed the pendulum to swing too far, with the result that senior administrative posts in the hospital and public-health service, many of them filled by men of considerable clinical experience, are now the least well paid of all? It is possible that current negotiations may remedy this; though the refusal of the Treasury last week to agree to the salary increases proposed for Government medical officers does not encourage optimism.

---

[1] *Lancet*, 1949, ii, 1225.

Clearly, until this happens, any decision to pay the chest physician partly as a clinician and partly as an administrator must reduce the attractiveness of the specialty and make it harder to recruit to the service the men of foresight and ability needed if this foremost of disabling diseases is to be brought, and kept, under control.

ON WASHING THE DISHES

THERE are few of us who are not now adepts at the kitchen sink; we have not even the privilege of grandfather's butler who condescended to deal only with the glass, silverware, and cutlery, sending the greasy plates to the kitchen for some lesser minion to cleanse. Today most of us are prepared not only to wash the plates and implements from the dining-room table but to furbish the pots and pans and the roasting tin as well. We have even learned the correct technique whereby glasswear, silver, side-plates, pudding plates, cutlery, and meat plates follow in due order lest the grease from the last-named contaminates the lustre of the first. The work is not arduous; the company of a congenial dryer makes it pleasant enough, though it wastes a lot of time. Nevertheless we have become a population at risk, for sink-work has hazards that lurk in the sodium carbonate or other detergent which so many of us splash all too lavishly into the washing-up water.

Dermatitis of the hands due to sensitisation to detergent solutions is one form of "housewife's dermatitis." Most dermatologists agree that this malady is now more often seen in outpatient departments and in private practice than before the war; but they are uncertain whether the increase is more apparent than real—whether, in fact, they are seeing more cases only because many more of the population are now at risk, while the morbidity-rate really is about the same. They speak of the hazards of "green labour," which is an unflattering method of referring to those whose delicate skins have not been inured by experience to the risks to which they are exposed. The more erudite have been heard to discuss the effect of a low-protein and low-fat diet on the defence mechanisms of the body.

Be this as it may, certain matters undoubtedly deserve attention. The first is that all household detergents tend to remove the natural greases from the surface of the skin; and, as these are necessary for the integrity of the horny layer, frequent exposure to them—particularly if they are used in unnecessarily high concentrations—may easily make the epidermis vulnerable so that sensitisation can occur. Accordingly the concentration of detergent in the water should be minimal. As to the nature of the detergent used, it would be invidious for us to recommend one we believe to be the safest. Let each try for himself; he can soon discover which detergents leave the hands dry, uncomfortable, and chapped, and those which perform their function adequately yet with little harm. In addition a good deal may be done to protect the hands. Rubber gloves of the usual household variety are seldom satisfactory, for not only are they easily punctured, so that the solution seeps into the interior and forms a poultice, thus enhancing the wearer's risk, but the skin becomes sodden with sweat, while the breakage rate of the crockery rises. Recently a barrier cream of the invisible glove type, which presumably has a sodium alginate base, has become available to the public; it has many advocates. To do its work properly, a barrier cream must be applied carefully, particularly to the vulnerable areas, the backs of the webs and the backs and sides of the fingers, before the hands are immersed. Less efficacious, but none the less satisfactory, is a suitable cold cream kept at the bedside and applied last thing at night. A good one with an old-fashioned formula is made by emulsifying beeswax (8%), spermaceti (16%), and almond oil (56%), with borax (1%) in rose water.

If, despite these precautions, dermatitis develops, it is inadvisable immediately to presume that washing up is the cause of the trouble. A list of all the hazards to which one is exposed should be made, not forgetting that the antiseptics and even the spirit used in our profession are all sensitisers. By avoiding exposure to all irritants, and by using the usual remedies such as calamine lotion during the acute stage, with zinc cream or zinc and castor-oil ointment later, the average attack of dermatitis may be mastered in about three weeks. Then comes the time to make tests. The full routine of patch-testing may be employed, but it is usually less troublesome to immerse a little finger in a warm solution of the suspected detergent for one minute: if one is sensitised, a recurrence of the eruption is likely to follow within 24 hours. Thereafter one has only to avoid that detergent, or any other which has chemical affinities with it, and all will be well; but it is worth remembering that if one's skin becomes allergic to any detergent, polyvalent sensitivities to many similar hazards may readily be acquired; and for a while it will be best to confine one's domestic activities to the less hazardous job of drying.

THE PRESENT STATUS OF AUREOMYCIN

IN the eighteen months since 'Aureomycin' was introduced by Duggar in the U.S.A. about a hundred papers on it have been published. It is unfortunate that lack of dollars is limiting supplies in this country, though the shortage at least ensures that the drug is used only in carefully planned trials or for the established indications. The American experience suggests that aureomycin will be one of the most valuable antibiotics in general medicine. Its range of activity is wider than that of any other antibiotic; it is effective against many gram-positive and gram-negative bacteria, and also against rickettsias, spirochætes, and even some viruses; it can be given by mouth; and it has been judged practically free from side-effects, the only troublesome ones reported being nausea and vomiting, sometimes with epigastric distress and a burning feeling in the rectum. However, Harris [1] reports rapidly developing mucous-membrane changes in many female patients, attributed to vitamin-B deficiency through destruction of intestinal bacteria—a complication also associated with administration of chloramphenicol. As a rule patients who cannot tolerate aureomycin by mouth experience no unpleasant effects when it is given intravenously. Owing to its bacteriostatic action on the bacteria of the gut, one peculiar effect of the drug is to produce soft and almost odourless stools. When given by mouth aureomycin is absorbed into the general circulation and is only slowly excreted: a dose of 0·5–1 g. will maintain an effective blood-level for about six hours. From the blood the drug is distributed to all the body-fluids and tissues, including the urine, cerebrospinal fluid, pleural fluid, and bile, and it also reaches the fœtus in utero via the placenta.

---

[1] Harris, H. J. *J. Amer. med. Ass.* 1950, 142, 161.

Many gram-positive bacterial infections have responded favourably to aureomycin even where the strains were resistant to penicillin and streptomycin. So far there is no evidence that aureomycin-sensitive organisms can become resistant. The drug has proved effective in bacterial pneumonias, including those due to pneumococci, staphylococci, streptococci, and *H. influenzæ*, and in meningococcal infections. Superficial staphylococcal infections, staphylococcal bacteræmia, osteomyelitis, and infections complicating leukæmia and other blood dyscrasias have been successfully treated. Experimental studies show that aureomycin is active against β-hæmolytic streptococci and also against *Strep. fæcalis*: in subacute bacterial endocarditis due to *Strep. fæcalis* or streptococci of the viridans group it is particularly useful when penicillin or streptomycin have been ineffective. Gonorrhœa responds to aureomycin, but the drug of choice in this infection is still penicillin. Like chloramphenicol, aureomycin seems to cut short the acute stage of whooping-cough, and if this is confirmed we shall have a choice of two remedies, both effective by mouth, and these may control the disease more surely and conveniently than prophylactic vaccination: time will show. Typhoid and other salmonella infections have not responded dramatically to aureomycin, but it is highly effective against *Bact. coli* and the clostridia, and so is valuable in general peritonitis following appendicitis or perforated ulcer. It looks like having a definite place in the treatment of urinary infections due to *Bact. coli*, *Strep. fæcalis*, *Bact. ærogenes*, and staphylococci, and it is most effective in acid urine. *Proteus vulgaris* and *Ps. pyocyanea* are resistant. Non-specific urethritis responds to the drug, the pleuropneumonia organisms disappearing rapidly from the urethral discharge; and the other bacterial infections that respond include tularæmia, brucellosis, anthrax, and bacteroides infections. Because of its greater activity by mouth, aureomycin may supplant penicillin in the prophylaxis of rheumatic fever. It also has a place with penicillin in the preoperative management of patients with organic heart lesions, for the prevention of bacterial endocarditis.

The value of aureomycin in some virus and rickettsial infections is beyond dispute. It produces rapid improvement in lymphogranuloma inguinale; and so far, after six months or so, no relapses have been observed.[2] In primary atypical (viral) pneumonia clinical improvement often occurs within 24 hours and fever subsides in 12–48 hours. Acute bronchiolitis or pneumonitis of infants, which is also probably a viral infection, responds to aureomycin better than to any other antibiotic or chemotherapeutic agent. Since aureomycin is effective n the treatment of the bacterial as well as the nonbacterial pneumonias, it is probably the drug of choice whenever a case of pneumonia has to be treated without aboratory facilities. Its first trial in herpes zoster has been dramatically successful.[3] The virus of psittacosis is ensitive to aureomycin, but human cases are so rare hat its effect on the clinical course of the disease is not known. Some cases of infective mononucleosis have shown a favourable response to aureomycin, but the rug is without effect in poliomyelitis, influenza, and the ommon cold. Information on its value in variola and accinia is scanty; but it is not expected to be of value n these and other conditions caused by small viruses. ts action against rickettsial infections has now been learly demonstrated in human Rocky Mountain spotted fever, epidemic typhus, murine typhus, Q fever, and rickettsial pox.

Certain ocular infections appear to respond to aureomycin given locally and by mouth. These include onjunctivitis due to various organisms and inclusion bodies, dendritic ulcers, superficial punctate keratitis, epidemic keratoconjunctivitis, and trachoma. Aureomycin is active against the spirochætes of relapsing fever (*Borrelia novyi*), leptospirosis (*Leptospira icterohæmorrhagiæ*), and syphilis, in which its use is still experimental, although one recent report indicates that in neurosyphilis it may be superior to penicillin.

This list is certainly impressive. With penicillin, streptomycin, and aureomycin at our command, there are now very few infections that cannot be controlled.

INFIRM AND OLD

MANY of our old people, though perhaps a little slower in their movements, are as active as the rest of us and enjoy looking after themselves and an occasional grandchild. Others are unfortunately helpless and bedridden. But between these two fairly clear-cut groups there are many who waver between health and sickness, and who need some help to tide them over the days when they do not feel so well. Like Scott's minstrel, they still enjoy the music but they need a boy to carry the harp. At present their needs are apt to be neglected, for when they are ill the people who look after them under the National Health Service are not the same people as those who help them under the National Assistance Act when they are well. The National Corporation for the Care of Old People[1] have therefore decided next year to pay special attention to the needs of the infirm and old. From the £1 million which the people of South Africa have given this country they have been asked to distribute £170,000, and they are to use this money to establish rest homes. For this purpose £50,000 has already been given to the government of Northern Ireland, and a small home has been opened near Glasgow for whose maintenance the regional hospital board has accepted responsibility; but on the whole the corporation have been disappointed by the apathy of statutory bodies, who tend to be so strict in their stewardship of public money that public needs get overlooked. The corporation also hope to start short-stay homes for elderly people so that the relatives with whom they live may have a chance to have a break. In all these ventures the corporation seek to signpost paths along which voluntary workers and statutory bodies may march together. At present coöperation between the two is apt to be hesitant, but the corporation, while frankly admitting the difficulties, believe that the job of looking after these old people can only be done effectively if it is shared.

ICELAND'S HEALTH

MEDICAL care is provided in Iceland under the National Insurance Act of 1936, which, besides sickness, covers accident, disablement, and old-age insurance. In the towns insurance against loss of health is compulsory, but in rural districts the parish councils have only permissive powers and may only adopt compulsory insurance if a majority is obtained after a general vote. According to the health report for 1945, which has just been published, 52% of the population are insured. There are 47 hospitals in the country, which provide 9 beds per 1000 inhabitants, and during the year the days in hospital amounted to 3·2 per head of the population. Under the Birth Control Act, which has now been in force fifteen years, 45 artificial abortions were undertaken during 1945; in 17 social as well as health reasons were taken into consideration.

DR. E. E. POCHIN will deliver the Oliver-Sharpey lectures at the Royal College of Physicians of London, on Tuesday and Thursday, March 14 and 16, at 5 P.M. He is to speak on Investigation of Thyroid Function and Disease by the Use of Radioactive Iodine.

Special Articles

ACCIDENTS IN THE HOME

OLIVE M. CASTLE
B.A. Camb.
MEMBER OF THE CHIEF SCIENTIFIC ADVISER'S DIVISION,
MINISTRY OF WORKS

THE Registrar-General's figures show that, even in recent years, there have been more deaths from domestic accidents than from accidents on the roads. Yet, apart from burns, the accidents that occur in the privacy of the home receive relatively little attention. The purpose of this article is to indicate the commonest causes of home accidents, and to draw attention to the amount of medical treatment they require and the human suffering for which they are responsible. The investigation on which the article is based forms part of a wider study of domestic accidents made by the Chief Scientific Adviser's Division of the Ministry of Works, assisted by an advisory panel under the chairmanship of Prof. J. M. Mackintosh.

The sample studied comprised all the home accidents treated at the Birmingham Accident Hospital during two months of each quarter of 1946, accidents in gardens being excluded. In all, 2909 cases were studied, and information on the history and subsequent treatment was obtained from their clinical records. In addition 100 patients were interviewed, while they were attending hospital in 1947, to obtain more detail than was given in the records. A similar but less detailed study of home accidents in 1948 showed that 1946 was not an exceptional year, the main findings being the same.

THE PATIENTS

The hospital serves a wide area, and patients either come for treatment directly or are referred by general practitioners from all parts of Birmingham and its environs. Of the 2909 patients, 44% were women and girls over the age of 14, 17% girls aged 14 or under, 18% men and boys over 14, and 21% boys aged 14 or under. That there should be more women patients than men is to be expected since women on the whole spend more of their time in the home.

A more striking fact is the high proportion (38%) of children aged 14 or under. The proportions of adults and children in the population at risk are not precisely known, but the Social Survey inquiry [1] of 1945 provides a useful picture of the population of the Midland Region, a large area including Birmingham. The age and sex distributions of the home accidents are compared with those of this population in table I, the most outstanding feature of which is that 22% of the accidents happened to children under the age of 5 years, though such children constitute only 8% of the total population.

TABLE I—AGE AND SEX DISTRIBUTIONS OF HOME ACCIDENTS COMPARED WITH THOSE OF THE POPULATION OF THE MIDLAND REGION IN 1945

Age (years)	Male (%)		Female (%)		Either sex (%)	
	Acc.	Pop.	Acc.	Pop.	Acc.	Pop.
0–4 ..	12	4	10	4	22	8
5–14 ..	9	7	7	6	16	13
15–64 ..	16	33	36	37	52	70
65 or over..	2	4	8	5	10	9
All ages ..	39	48	61	52	100	100
No. of cases	1139		1770		2909	

The fact that more accidents happened to boys than to men is partly explained by boys spending longer in the home; a similar reason, however, is less likely to explain the large number of accidents to girls. It seems, therefore, that children are more likely to experience home accidents than adults, and that the risk is particularly high in children under 5 years. The risk to girls appears to be very little, if any, less than that to boys.

THE ACCIDENTS

Of the 2909 home accidents, 42% were due to the patient falling, 36% to collision with household objects (fittings, furniture, tools, and equipment), 13% to burns and scalds, and the remaining 9% to miscellaneous causes.

Falls

The 1219 falls were classified as follows:

Type of fall	*No. of cases*
Unspecified	612 (*0*%)
On stairs or fixed steps	276 (*23*%)
Off furniture, out of bed or perambulator ..	123 (*10*%)
From heights	72 (*6*%)
Twisting injuries of ankle	44 (*4*%)
Other falls	92 (*7*%)
Total ..	1219

Of those falls for which details were available, nearly half occurred on stairs or fixed steps within the home. Most of the falls on staircases took place when the patient was coming downstairs. Of 19 patients interviewed, 12 had fallen on stairs, 2 down cellar steps, and 5 on odd steps inside the house or leading to the street or yard.

Both mechanical and human factors seem to have contributed to these accidents. Several falls were attributed to the structure of the stairs; they were steep and winding, or a bedroom door opened directly on to them. In other instances the stairs were dark; they had no natural lighting and very poor artificial lighting—e.g., an electric light in a room at the top of the stairs but not over the stairs themselves. Cellar steps were completely dark, and one flight opened directly off an ill-lighted passage without any door or partition. Some patients claimed that the condition of their footwear probably caused the accident—their shoes were either old and in bad repair, or were too big, or had slippery soles. Of the human factors, illness and physical handicap were the most prominent, and inadequate supervision on the part of the parents was sometimes responsible for accidents to small children.

Falls off furniture and out of bed or perambulator constituted another major group of accidents. Many of these were due to the misuse of the furniture in question; it was often found that patients had been standing on the arms of chairs or on tables to reach curtains or objects at a high level, and that the chair or table had overbalanced.

The accidents to children generally took place when the children were playing—sometimes they were swinging on pieces of furniture or jumping about on their beds—in nearly all cases the accidents were the outcome of high spirits and excitement.

Another fairly common type of fall was from a height—usually from steps, ladders, or window-sills. These accidents happened to men and women equally. The only 4 patients in this category who were interviewed were adults who had fallen off steps, and 3 of them attributed the fall to their own carelessness, either because the steps were not placed firmly on the ground or because they were old and in bad repair.

There were many more injuries arising from falls, of such variety as almost to defy classification. Among adults, particularly women, injuries of the ankle were commonly caused by walking with unduly high heels or on uneven surfaces.

---

[1] Social Survey Inquiry 1945. Population and Housing, England and Wales (Civil Defence Region 9—Midlands).

In elderly or infirm patients it was often clear that their physical frailty was largely responsible for the fall; for some of them walking, even in the house, needed a real effort. But many of the patients who had fallen were young and robust, and in these cases, interviews revealed consistently that shoes were to blame. With remarkable regularity it was learnt that new and unfamiliar shoes were being worn and that the accident was the result of a combination of slippery soles, a highly polished floor, and a desire to make haste. Shoes in bad repair or lacking laces or other fasteners were mentioned in a smaller number of cases.

Injuries from Household Objects

In a great variety of home accidents the injury (often a laceration) resulted from collision with an inanimate object. Classification was not always easy, and the designation of the various groups was a problem in itself. The 1054 accidents of this type were as follows:

Type of injury	*No. of cases*
Striking against objects	239 (*23%*)
Injury by cutlery, tools, tin-openers, &c. ..	272 (*26%*)
Injury by glass and windows..	141 (*13%*)
Being struck by moving objects	111 (*10%*)
Tripping over objects	60 (*6%*)
Injury from doors	60 (*6%*)
Injury from domestic machinery	36 (*3%*)
Other injuries	135 (*13%*)
Total ..	1054

Many of the injuries were caused by the patient slipping or stumbling against the object, or striking it with his hand, arm, or leg. The objects most often concerned were bedsteads, chairs, and other furniture; walls and staircases (particularly sharp corners) were often mentioned, and collisions with sinks, gas stoves, fenders, and buckets were also common. Small protruding nails and pieces of metal were among the objects which, though apparently insignificant, caused severe injuries. Injuries from striking against objects formed 8% of the 2909 home accidents of all kinds. They occurred in all age-groups, women being involved far more often than men, but boys more than girls.

A more clearly defined group of accidents were due to knives, razors, needles, and other sharp instruments; these made up 16% of all the injuries from household objects, and the incidence was particularly high among boys of school age. The majority were lacerations from knives, bread-knives or carving-knives being mentioned in roughly a third of the cases.

A further 10% of all injuries from household objects were caused by tools, tin-openers, and other implements of this kind. The tool most frequently involved was the chopper. Cuts from tins were nearly as common, and they usually occurred when a tin was being opened. Injury from tools is the only type of accident for which the risk appeared to be greatest among adults (aged 15–64); it is also the only group with a significantly higher number of men than women.

These last two groups (injuries from cutlery and from tools) consisted largely of accidents which happen at intervals to a high proportion of the population, but of which many are not serious enough to need hospital treatment. Yet, since there were 272 of them in these 2909 home accidents, and since many of them required repeated visits to the hospital, they cannot be dismissed as unimportant.

Glass was another source of many accidents, and for convenience all accidents in which windows were involved are discussed in this category, whether or not the injury was caused by a pane of glass. This group covers 13% of all accidents from household objects; roughly a third of these involved windows and a fifth were caused by broken bottles. Most of the patients who had been injured by windows were women, and a high proportion of the accidents resulted from broken sash-cords—when the patient opened the window it fell and dropped o hands. Other patients had put their hands or el through windows, sometimes while they were cle them.

Other common sources of injury were splinters, f objects, and objects lying on the floor and ca patients to trip. Elderly people were particularly to this last type of accident; they often tripped loose mats and uneven floorboards or linoleum.

Injuries from doors and from domestic mach were quite common, particularly in small children. children injured by a door had usually shut their fi in it, but some had been very close to the door and been injured when someone else opened or shut it. domestic machinery, the greatest cause of accidents the mangle; this seems to be an attraction to small children, and it also caused several injuries to h wives. Sewing machines were mentioned less often.

A boy, aged 2 years, hearing his mother using the m in her kitchen, ran in from the garden and, before she stop him, put his fingers between the wooden rollers she was turning them. When not in use the mangle is c with safety catches to prevent the child from opening it.

Burns and Scalds

Of the 2909 accidents, 13% were burns and sc Many scalds (42%) were caused by the spilling of liquids; the patients were mostly small children, about a fifth of the cases were caused by the c clutching a saucepan handle or the corner of a tablec and thus upsetting the hot liquid over himself.

A boy, aged 1 year, who was alone in a room, jumped a in his perambulator, which moved towards a table. child clutched the overhanging tablecloth and pulled a of tea on to himself.

Many burns and scalds (16%) were caused by patient touching a hot object, such as an electric iron the bars of a grate, or parts of a cooker. A further 1 were the result of the patient falling on to a fire, an about a quarter of these cases his clothing was set ali Other burns were caused by hot coals, naked flames, explosions when gas ovens were being lit.

A boy, aged 1 year, was in the living-room with his fat who was reading. An electric iron, switched on, was stan on the sideboard. The child pulled the lead, which stretched across the room, and the iron fell on to his fac

Many burns and scalds were a direct result of ina quate protection of children from sources of heat.[2]

TABLE II—COMPARISON OF CAUSES OF FATAL AND NON-FA HOME ACCIDENTS

Type of accident	No. fatal*	No. non-fatal
Falls:		
On stairs	711 (*12%*)	276 (*10*
Off steps, ladders, &c.	194 (*3%*)	72 (*2%*
All others	1500 (*25%*)	871 (*30*
Total ..	2405 (*40%*)	1219 (*42*
Injuries by household objects:		
Cutting and piercing instruments..	12	272 (*9%*
All others	0	782 (*27*
Total ..	12	1054 (*36%*
Burns and scalds:		
Fall on fire	74 (*1%*)	31 (*1%*)
Clothing on fire	385 (*6%*)	12
Flames, explosions, &c.	104 (*2%*)	39 (2%)
Scalds	202 (*3%*)	171 (*6%*)
Other burns	273 (*5%*)	119 (*4%*)
Total ..	1038 (*17%*)	375 (*13%*
All other causes	2541 (*43%*)	261 (*9%*)
Grand total ..	5996	2909

AGES AT WHICH RISK OF INJURY IS GREATEST

For nearly all types of accident the risk is greatest to children under the age of 5 years. The following are the only types of accident where the risk seemed greater in some other age-group :

Type of accident	*Age-group with greatest risk (years)*
Injuries by cutlery, razors, &c.	5–14
Injury by choppers, tools, &c.	15–64
Injury from windows	over 65
Injury from tripping over objects	over 65
Splinters	5–14

Types of accident where the risk to children under school age was particularly high were falls out of bed and off furniture, burns and scalds, injuries by domestic machinery, and injuries from doors.

A more detailed study of the actual frequency (as distinct from the relative frequency) of accidents to children under the age of 5 years showed that children aged 2 years had the greatest number of accidents. Unspecified falls were prominent at each age. The most common causes of accidents for each year of age were as follows :

Age (years)	*Commonest type of accident*
0–1	Scald from hot liquid spilt Burn from hot object
1	Fall out of bed or off furniture Scald from hot liquid pulled on to self
2	Fall out of bed or off furniture Fall on stairs
3	Fall out of bed or off furniture Injury by striking against object Fall on stairs
4	Scald from hot liquid spilt Injury by striking against object

Types of accident which had a relatively high incidence among elderly people were falls (particularly on stairs, out of bed, and off furniture), injuries from windows, and from tripping over objects.

SEVERITY OF INJURIES

Of the patients studied, 95% were treated entirely as outpatients. The proportion of patients admitted to the wards ranged from 17% with burns and scalds to 3% with injuries from household objects. Inpatient treatment was received for 4% of the falls, the most serious in this respect being those on stairs and from heights. Well over 10% of the patients with burns or scalds were admitted as inpatients, but with burns from direct contact with fires the proportion admitted was particularly high (50%), and 4 of the 5 deaths in the series were the outcome of burns of this sort.

The seriousness of burns and scalds among domestic accidents is further emphasised by comparing the distributions of fatal and non-fatal home accidents according to type. In table II the Registrar-General's figures for deaths due to home accidents in England and Wales in 1945 are classified in the same way as the 2909 " non-fatal " accidents treated at the Birmingham Accident Hospital, and the distributions expressed as percentages of the total number in each sample. The fact that 5 of the 2909 cases were fatal does not affect the validity of the comparison. It will be seen that the proportion of " falls " in all three subgroups is similar for fatal and non-fatal accidents. " Burns and scalds," however, form a higher percentage of the fatal than of the non-fatal accidents ; this difference is particularly pronounced for burns from clothing on fire, such accidents forming 6% of all fatal accidents but less than 1% of the non-fatal sample. This is an example of the type of accident which is uncommon compared with all other types of home accident but so serious that it causes 6% of all deaths due to accidents in the home.

TABLE III—DURATION OF TREATMENT

Type of accident	Inpatients			Outpatients		All patients
	No. of cases	Median duration (days)		No. of cases	Median duration (days)	Mean duration (days)
		In-patient treatment	Out-patient treatment			
Falls	17	22	21	1172	15	34
Injuries from household objects	27	16	32	1027	8	18
Burns and scalds	62	21	9	313	7	22
Miscellaneous ..	4	25	1	257	4	16
Total ..	140	20	17	2769	9	25

The other side of the picture is shown by comparison of fatal and non-fatal figures for " injuries by household objects " ; here we have a large source of minor injuries which rarely lead to death.

Duration of treatment (number of days from first to last visit to hospital) is another measure of the severity of the cases ; average values for different types of accident are given in table III, which shows median durations for inpatients and outpatients separately, and mean durations for all patients. (The median is the middle value when the durations are arranged in order of magnitude, whereas the mean is the sum of all the durations divided by the number of patients ; the *median* is the better measure since it is not affected by the few patients whose very long treatment times are not a true estimate of their disability.)

Table III shows that for both inpatients and outpatients the period of treatment was longest for falls. The facts that most fractures occurred in this group and that fractures required the longest treatment were probably responsible for this.

The length of treatment required for injuries caused by falls, together with the large number of such accidents (42% of 2909), emphasises the importance of this type of accident from the point of view of the time lost by home accidents. The median of 15 days represents an average of eight visits to hospital and considerable limitation of working hours.

The over-all medians for all types of home accident for inpatients were 20 days in the wards followed by 17 days' outpatient treatment ; and for outpatients 9 days' treatment involving five visits to hospital. The mean duration for all patients was 25 days. Hospital treatment lasting at least a fortnight was required by 40% of the outpatients, and in 15% of the cases the treatment lasted six weeks.

Some idea of the amount of medical treatment required by injuries received in the home is revealed by the total treatment times. The 140 inpatients were in hospital for a total of 4685 days—in other words, throughout the eight months 20 beds were used exclusively for home accidents. The 2769 outpatients made 14,000 visits to hospital, representing visits of 58 patients a day.

INCIDENCE OF HOME ACCIDENTS

The seriousness of home accidents can only be realised when we have some idea of how many people are involved. From the Registrar-General's figures for accidental deaths we learn that, in 1945 and 1946, for every 70 men, women, and children killed in road accidents in England and Wales 100 were killed in accidents in and *around their homes* ; and that domestic accidents accounted for 6000 deaths in England and Wales in each of these years. But we do not know how many more thousands of adults and children were seriously injured, or how many received injuries which, though not serious, nevertheless required treatment, possibly over a long period and at considerable inconvenience to the patient and his family.

That the number of non-fatal home accidents is large is indicated by the fact that 5000 cases were treated in 1946 at the Birmingham Accident Hospital alone; in 1948, this figure rose above 6000. These figures do not give a rate of incidence of home accidents, since many of the accidents occurring in the Birmingham area are treated at other hospitals or by private doctors.

To estimate a rate of incidence a study has been made of a small area round the hospital (Bath Row area) for which it might be supposed that nearly all home accidents requiring treatment would report to the Birmingham Accident Hospital. To establish a rate of incidence of home accidents it was necessary to know both the population of the area and the number of accidents.

During the summer of 1946 the public health department of the Birmingham city council made a housing survey of the whole city, in the course of which the number of inhabitants of each house was obtained. The medical officer of health kindly allowed me to study these population figures and it was therefore possible to obtain, for each street of Bath Row area, the total population in mid-1946.

Examination of the addresses of the 2909 patients considered previously gave the number of home accidents occurring in Bath Row area and reporting to the Accident Hospital in eight months of 1946. Since some cases may have been treated elsewhere, this was a minimum estimate of the number of accidents which happened.

Bath Row area was chosen by inspection of a map on which the addresses of 1000 of the 1946 patients were plotted, and the choice was subsequently supported by consideration of rates of incidence in small areas on either side of its boundary. It covers about a third of a square mile, and every house is within half a mile of the hospital. Since the nature of the area probably influences the number of home accidents, a description of the most prominent local characteristics follows.

Bath Row area consists mainly of court and terraced houses 90–110 years old. Many of them are three-storey houses, some are of the back-to-back type, and very few have gardens. The area includes some scattered industrial property, particularly along the north-west boundary and in the northern corner. The whole area is scheduled for redevelopment; the houses are close to one another, and no stretch of ground is free from buildings. The density of population here is 60 persons per acre, compared with an average of 20 persons per acre for the whole city, and this small area houses nearly as many people as the whole of the county town of Warwick (13,000).

It was found that 350 accidents from this area were treated at the hospital in the period reviewed, giving a rate of 2·7% of the population of 13,000 for eight months of 1946, corresponding to 4% per annum. This means that, in 1946, 4% of the inhabitants of Bath Row area reported to the Birmingham Accident Hospital with accidents sustained in their homes.

The proportion of children under the age of 10 years was 40% among the patients, though only 20% in the population. The high risk to young children is made clear when it is realised that the over-all accident-rate of 4% is made up of 3% of the population aged 10 years or more and 9% of the children under the age of 10 years.

Among the patients from Bath Row area there was a higher proportion of children and fewer elderly people than in the whole sample of 2909 cases, but this was partly because of the high proportion of children in Bath Row area. The cases were, on the whole, less severe than those of the full sample; the proportion of inpatients was 4% compared with 5%, and the distributions according to duration of treatment were as follows.

Duration of treatment (days)	*Percentage of patients*	
	Bath Row (350 cases)	*Full sample (2909 cases)*
1	35	25
2–9	32	25
10–27	23	25
28 and over	10	25
Mean duration	11 days	25 days
Median duration	5 days	9 days

The lower average severity for Bath Row is to be expected; minor accidents which happen at a great distance are unlikely to come to the hospital for treatment. Nevertheless, the 14 inpatients from Bath Row area occupied beds for 266 days in the eight months; so one bed was used throughout the period, and two beds for some of the time, for home accidents from this area alone.

Of the 350 cases, only 8 were of patients who had two accidents during the eight months for which records were used. This suggests that accident proneness was not a major factor, but the period considered was too short to provide conclusive evidence on this point.

COMMENTS

It is disquieting to learn that the home is so often the place where members of the family receive accidental injuries. In this area of 13,000 inhabitants at least 9% of the young children and 3% of older children and adults received hospital treatment for such accidents in a year. Caution is needed in applying these rates to other districts; in less densely populated areas, in modern housing estates, or in better-planned houses, it might be expected that fewer accidents would happen; information on this point would be valuable. But the large number of cases reporting from all parts of Birmingham suggests that the total rate is far from negligible; moreover, districts comparable with Bath Row area exist in both large and medium-sized towns, and the home-accident rate is unlikely to be consistently higher here than elsewhere. The effects of these accidents on the patients and on their families, and the amount of medical attention and treatment which they require, call for immediate efforts for prevention.

In a review of 1000 cases of burns and scalds Colebrook and Colebrook[2] have pointed out that a high proportion of these accidents took place in the home, and that half of these could have been prevented "given reasonable care and foresight on the part of the adult concerned, whether victim or guardian." The present study of a smaller number of patients with burns and scalds, many of whom were treated entirely as outpatients, suggests the same pointers to prevention. Conversation with some patients and parents revealed that they had not realised that gas and electric fires were as great a source of danger as open coal fires, and therefore needed fireguards, particularly in small rooms where members of the household are likely to pass very near to the fire; nor had they always thought of the danger of leaving bowls and pans of hot liquid within reach of children. Education in measures of protection is urgently needed.

Many kinds of fall are equally preventable. If staircases had good artificial lighting which could be switched on at either floor, firm handrails at each side (particularly at the outside where a staircase winds), and a carpet or other covering firmly fixed and without holes or uneven surfaces, the risk of accidents on stairs would be greatly reduced. The continual supervision of toddlers who are at home all day presents a problem to many mothers, and this may be eased and accidents prevented by the provision at *each* end of the staircase of small lightweight gates which can easily be removed when the children are no longer tiny.

Elderly people, too, need special consideration. Sheldon[3] has drawn attention to the "great importance in old people of the effects of falls and accidents, because of the severe injuries that may follow; in some cases a fall may precipitate a general break-up of the old person"; the present study supports his suggestion that old people are particularly liable to trip over small objects and may thus sustain severe injuries.

---

[3] Sheldon, J. H. The Social Medicine of Old Age. London, 1948.

There is evidence that odd steps in the home are a hazard; going up or down a staircase one adjusts one's stride to a convenient length, but single steps are more easily ignored or even not noticed. This is a feature which cannot easily be changed in existing houses but could well be avoided in future building.

The importance of footwear as a cause of accidents is appreciated only by those whose shoes have caused them to fall. Unfastened shoes, and shoes which have lost their laces or are otherwise in bad repair may cause their wearer to stumble and fall, and accidents from this cause could often be avoided if the danger were more widely known. The slippery soles of new or newly repaired shoes considerably increase the chances of falling, and the more general provision of soles with a rough surface, possibly comparable to inverted calf, or scratched leather, would prevent many injuries as well as removing the feeling of instability which new shoes promote in elderly people.

A greater awareness of the risks attached to the use of equipment in a bad state of repair would prevent many of the accidents caused by household objects. It is folly to use a pair of steps with a broken strut, or a chopper with a loose head. But not all these accidents are the result of gross carelessness, and much could be done by improving the design and placing of fittings in the home, and by avoiding the use of shelves and cupboards beyond the reach of the housewife; doors which foul, windows which are not easily opened or conveniently cleaned, and, perhaps most of all, overcrowding, which "makes it difficult to keep dangerous things in safe places and to prevent children from interfering with them"—all these factors contribute to the total of home accidents.

SUMMARY

A study of nearly 3000 cases of home accidents treated at Birmingham Accident Hospital in 1946 showed that 42% were falls, 36% injuries from household objects, and 13% burns and scalds. Falls on stairs and fixed steps and injuries from knives and tools and from striking against furniture and fittings were particularly common. Falls off furniture and scalds from the upsetting of hot liquids were nearly as common.

Two measures of severity of the injuries have been used: (1) the proportion of cases receiving inpatient treatment, which was highest for burns and scalds (17% compared with an average of 5% for all types of accident); and (2) the total duration of treatment, which was highest for falls (mean of 34 days, compared with an over-all mean of 25 days).

For nearly all types of accident the risk seems to be greatest for children under the age of 5 years. Of a population of 13,000 living in a small area surrounding the hospital, 9% of those under the age of 10 years and 3% of those over that age were treated for home accidents at the hospital in 1946.

The following factors contributed to the causes of many accidents:

Inadequate lighting and other defects of staircases.
New shoes, and shoes in poor repair.
Misuse of equipment, use of faulty equipment, and inconveniently placed fittings.
Hot liquid left within reach of children.
Lack of guards to gas, electric, and open coal fires.

I am indebted to Mr. W. Gissane, F.R.C.S., clinical director of the Birmingham Accident Hospital, for permission to use the hospital records and to interview patients; the director and members of the Medical Research Council Industrial Medicine Research Unit, Birmingham Accident Hospital, for valuable help at every stage of the work; and the Medical Officer of Health and Mr. D. J. E. Lamb, chief housing inspector of the City of Birmingham public health department, for their cooperation in supplying population figures and other helpful information.

STUDENT HEALTH IN CAMBRIDGE

THE Cambridge University health service, which started work at the beginning of the Michaelmas term, 1948, began as the result of a pilot survey which Sir Lionel Whitby, the regius professor of physic, made in 1947 of the health of the undergraduates of two colleges. This survey showed that minor disabilities are common in the undergraduate population, and that a few cases of serious disease may be found lying latent and possibly acting as source of infection.

The new service was at first part of the department of medicine, but it was transferred to the department of human ecology when it assumed autonomy on the appointment of Dr. A. L. Banks to the chair. Health officers for the service were appointed in the summer of 1948, and Sir Alan Rook, the senior health officer, in his recent report,[1] describes the first year's working.

HEALTH EXAMINATIONS

The service is on a voluntary basis and is limited to preventive measures; treatment, hospitalisation, and specialist services remain in the hands of the local doctors. At first only freshmen and women were eligible to join the service. Circulars describing the aims of the service were sent to all men and women joining the university in the Michaelmas term, and 1858, roughly three-quarters of the total entry, volunteered to join. On each an X-ray examination of the chest, and a short clinical examination was carried out.

Radiography.—Among the 1751 freshmen and women who were X-rayed 3 cases of pulmonary tuberculosis were found who required transfer to a sanatorium for immediate treatment, and 19 cases with lesions requiring observation while they carried on with their studies. Later in the academic year an opportunity was given to senior men and women to have their chests X-rayed. Among 1533 volunteers there were 2 cases of pulmonary tuberculosis requiring immediate treatment and 17 requiring observation.

The X-ray examination of rather less than half of the undergraduates therefore disclosed 41 cases of pulmonary tuberculosis in need of observation or immediate treatment. A number of non-tuberculous conditions were found, the principal ones of interest being 2 cases of sarcoidosis and 1 of neurofibroma.

Clinical examinations.—The time for the clinical examination had to be limited to thirty minutes, which is only long enough to allow a rapid survey of the various systems of the body. To avoid unnecessary delay a history questionnaire was given to everyone coming for radiography. Forms were filled in and were available for perusal before the clinical examination. Among the 1583 men and 144 women who were examined a comparatively large number of minor disabilities were found. To some it was possible to give advice during the interview; others were referred to their own doctors; in emergency, specialist advice was obtained if the student's own doctor did not live in Cambridge.

The value of this part of the examination lies in the opportunity which it gives of having a short private talk with each undergraduate, for it is in this way that the most effective form of health teaching can be given. The number of young people who imagine quite erroneously that something is the matter with them, usually with the heart, is far from inconsiderable. At the other end of the scale were 3 undergraduates who were found to have a previously unsuspected valvular lesion of the heart.

INCIDENCE OF ILLNESS

Dr. Alan McFarlan, the reader in human ecology, has also investigated the illnesses reported by college nurses who, with the sanction of the college tutors, have made weekly returns of the number of undergraduates seen by them during the period of full term. Scrutiny of these returns has provided useful information on the incidence of respiratory infections and the distribution throughout the colleges of intestinal complaints, boils, and injuries. The returns of gastro-enteritis cases are of particular value in assisting to take reasonable precautions to prevent epidemics. During the Easter term 48 cases of "tripos anxiety" were recorded, 25 in men and 23 in women. In future years the university health service, with the coöperation of the colleges, can hope to help in treating and preventing this anxiety.

---

RADIOTHERAPY IN THE HEALTH SERVICE

NEW arrangements for the distribution of radioactive substances under the National Health Service are announced by the Ministry of Health in a circular to hospital authorities.

The ownership of radium is to be vested in the Ministry of Supply. Application for supplies will be made to the Ministry of Health by regional boards or (through these boards) by management committees. All new radium issued to hospitals will be provided by the Radiochemical Centre on hire to boards of governors or hospital management committee; and hire charges, on both new and existing stocks, will be payable according to the radium content of containers or appliances at the rate of £225 per g. per annum.

In accordance with professional advice, the comparatively close control formerly exercised by the Radium Commission is to be continued. The Ministry re-emphasises the need for joint planning by regional boards and boards of governors. Hospitals which have had radium on loan from the Radium Commission undertook to make full reports to the commission; and these reports are in future to be submitted to the Ministry of Health.

Hospitals on a list prepared by the Radium Commission may continue to receive radon from the Radiochemical Centre, and the Ministry is prepared to consider applications for additions to the list.

Present arrangement whereby isotopes required for research may be obtained on application to the Medical Research Council remain unaltered. Uranium parts may be hired from the Ministry of Supply.

Under the Radioactive Substances Act, 1948, Ministers are empowered to make regulations to ensure the safe handling of radioactive substances and protection from dangerous radiation. The Ministry of Health will later issue to hospitals advice about protective measures.

MEDICAL SERVICES IN THE U.S.A.*

A. LESLIE BANKS

M.A. Camb., M.D. Lond., F.R.C.P., D.P.H.

BARRISTER-AT-LAW; PROFESSOR OF HUMAN ECOLOGY IN THE UNIVERSITY OF CAMBRIDGE

PERHAPS the first impression that the traveller in the United States gains is that the people are very different from Europeans. To the Britisher in particular the mixture of races is surprising, and he finds it hard to realise that this heterogeneous mixture can have an "American" outlook. He learns speedily that it has. Whatever the country of origin the loyalty is first and foremost to the United States. Thus when a man with a middle European name says that "we were all cowboys a hundred years ago" he is in deadly earnest. The New York taxi-driver born in Bristol, or the negro red-cap at the railway station or airport, are equally sincere when they declare their fervent belief in the American Way of Life.

This emphasis on the American way of life can be intensely irritating to the European and also rather puzzling. It is a compound of a mystical element, which may take the place of tradition in older countries, and of sound business common sense. Americans know the value of money to the last cent and the American way of life means to them the right to work where they please and to sell their services to the highest bidder.

The days of the pioneer are not yet over. The growth of new industries during and since the war has meant that millions of people have travelled to new areas. For example, at least $3^{1}/_{2}$ million, representing the greatest peace-time migration in the history of the world, have travelled to California within the last few years. Developments on the west coast are still proceeding, and these, and the enormous expansion of industry in other areas such as Texas, keep the pioneer spirit alive. Forty per cent. of the population are said to be always "on the move."

Though the outlook is, first and foremost, American, these racial groups present problems with which we in this country are not familiar. Not only may they have sentimental attachments to the country of their origin but they also form social and political pressure groups which may be extremely powerful. It is said that in New York there are more Irishmen than in Dublin, more Scandinavians than in Scandinavia, and more Italians than in Rome. Ten per cent. of the population of the States are negroes, and the proportion is much higher in some areas including the industrial cities of the north. These minority groups may develop an intense interest in one aspect of a legislative programme. For example they might view a proposed Bill from their own particular angle, and if they disliked some part of it they could bring tremendous pressure to bear on State and Federal legislators, together with the powerful machinery of publicity. Thus a Bill introduced for one purpose might at the last moment have a clause introduced at the instigation of a pressure group which would alter its whole character.

SIZE AND ORGANISATION

The next point to strike the visitor is the size and resources of the country. These are breath-taking to the Englishman and it is an extraordinary experience to fly by night from, say, Los Angeles to New York. The distance is about 3170 miles and the journey takes a little over twelve hours. For the whole of that time one is hardly ever out of sight of the twinkling clusters of stars representing towns and cities. A long journey by train is even more illuminating. Pessimists will say that the resources of the country are being used up so fast that they will be exhausted by 1970. It is true that vast areas of forest have been destroyed, that farm lands have been rendered useless by erosion, and that in the west and south-west the problem of inadequate water-supplies is very serious. But these problems are being tackled in herculean style. The T.V.A. scheme is only one of the outstanding examples of this. In other areas irrigation plans involving the diversion of rivers to provide water-supplies for places hundreds of miles away are under consideration.

It takes a long time for the stranger to understand the Constitution and political organisation of the United States. Historically the States came first, and they combined only reluctantly for the purpose of driving out the common enemy. Incidentally, Britishers should remember that, traditionally, they are that enemy. An elderly lawyer told me that he learnt history by being taught to hate the British. Fortunately it is now "ancient" history, but the effect has been that the States retain their sovereignty and are extremely jealous of the growth of Federal powers. Taxation is levied on the individual by the Federal government but there may be, in addition, State, city and municipal taxation. The centre of Federal government is Washington, D.C. Washington is some 3000 miles from California and about 1500 miles from the rapidly expanding south-west. On geographical grounds alone therefore there is justification for the fear of the more remote States that their problems may not be wholly understood in the legislative centre and that money taken from their citizens by Federal taxation may come back "with strings attached to it" which are not applicable to local conditions. There are other reasons for anxiety. The heads of the civil service in the State and Federal service do not have security of tenure. They may change with the Governor or with the President. Again, in a country with a population of 140 million people the incentive to political success is so great that the actions of a politician may be governed by the desire for power. Indeed, part of the intense fear of "Socialism" and "Communism" (terms the meaning of which are little understood in the States) is due to the recognition that it would not be impossible for unscrupulous and ruthless men to seize power.

---

* A lecture in a series entitled The Background of Medicine forming part of the postgraduate courses arranged by Cambridge University Medical School. The observations were made during a visit to eighteen university centres in the United States, made possible by the generosity of the Rockefeller and Nuffield Foundations.

Another consideration little understood in this country is the effect of the last war. The American people entered the war with high ideals. They came out of it victorious and feeling that at last peace had been secured for the world. The effect of the continuing cold war has been to engender a sense of frustration and a growing feeling of insecurity. The nation has been thrown into world leadership before it was ready for this. The combination of anxiety about the international situation, concern at the growth of Federal power, and the growing internal demands for social security explain much of the emotional reaction against things like "socialised medicine." No visitor to the United States can be there long without sensing this deep anxiety. Every man and woman in the States is also aware that America came out of the war 230,000 million dollars "in the red" and that the country is going deeper into the red—and this in spite of record prosperity. This money is being spent mainly on armaments and aid to foreign countries including Britain.

MEDICAL CARE : PRIVATE OR PUBLIC ?

It is against this disturbed background that the organisation of medical services must be studied. The practice of clinical medicine in the States is traditionally entirely a private matter between doctor and patient. Organised medical care is provided for veterans, the Indians, and the indigent, and also for patients with mental disorder, tuberculosis, and the infectious diseases. Outside these services the voluntary pattern familiar in this country before 1912 can still be recognised.

Perhaps the best indication of the changes in attitude since that time is given by the reactions of the American Medical Association. In 1912 the *Journal* of the A.M.A. is reported as saying that :

> "The important feature of the British Act (the National Health Insurance Act of 1911) is the recognition that it is the duty of society, as represented by the government, to furnish medical treatment for those who are unable to secure it for themselves. It also means the recognition of the modern physician as a health officer of the state, working for the general good, rather than a private or professional business man."

In 1915 various community sickness surveys showed the inadequacy of medical care in the States, and the social insurance committee of the A.M.A. reported that the logical conclusion was compulsory State insurance both for the benefit of the patient and "of the unfortunate physician facing starvation." In 1916 the committee was saying :

> "Blind opposition, indignant repudiation, bitter denunciation of these laws is worse than useless ; it leads nowhere and it leaves the profession in a position of helplessness if the rising tide of social development sweeps over them."

By 1919 the effect of war prosperity was becoming apparent, and in 1920 the A.M.A. declared its "opposition to the institution of any plan embodying a system of compulsory contributory insurance against illness." By 1922 this had hardened to opposition to all forms of State medicine. By 1924 government insurance had become "socialised medicine," "political medicine," "assembly-line medicine" and "peasant medicine." From then on the story is familiar to everyone. In 1929 government medical insurance was being described by the A.M.A. writers as "Communism," in 1939 as "Naz-ism," and in 1949 again as "Communism." In April of last year the chairman of the A.M.A.'s board of trustees described President Truman's medical insurance programme as "the discredited system of decadent nations who are now living on the bounty of the American people."

VOLUNTARY MEDICAL INSURANCE

On the face of it therefore the issue would appear to be a straight one between the reaction of the A.M.A. and the drive for compulsory health insurance by the President and his advisers. In fact it is nothing of the kind. There has been, over the past twenty years, an enormous extension of voluntary prepaid medical care schemes. For hospital care Blue Cross plans have expanded so rapidly that at least 40 million people are now covered, and a total of 60 million people are said to have some form of hospital coverage through the Blue Cross. The most significant development, however, has been the extension of group practice by the doctors to provide prepaid medical care. Some of these organisations grew out of the old despised contract practice. In spite of early opposition by the A.M.A., which described them as "medical soviets" and refused to give them the seal of recognition, these organisations have flourished exceedingly. Thus one county medical service corporation that I visited now has a 5 million dollar business turnover. Its administrative organisation would be the envy of any bureaucrat in this country, for it employs more than 100 clerks. 700 doctors are employed on a fee-per-service basis to minister to 140,000 people. The control is entirely medical, with full-time medical and assistant directors. The governing body is composed of doctors who decide the fees to be paid to their colleagues, lay down conditions of service, and undertake disciplinary measures. In the words of the assistant director, "the docs police the docs and deal with the chisellers." Any doctor not conforming to the accepted pattern is put on probation and at the end of that time his contract may be terminated.

These organised medical services have disadvantages from the patients' point of view. They are not cheap. The corporation already described now requires a payroll deduction of 10 dollars a month as opposed to 1 dollar a month in 1933, and benefits are only available while the worker is in full employment.

There is no doubt that organisations of this kind are profitable to the doctors but there have also been developments on non-profit-making lines. Thus the Health Insurance Plan for Greater New York provides comprehensive medical care to workers and their families at home, at doctors' offices, at medical group centres, and in hospitals. H.I.P., as it is called, was established in March, 1947, to provide this all-inclusive medical care, without regard to age, for a fixed premium with no surcharges. It is a voluntary non-profit corporation licensed under the insurance laws of New York. This type of development can be seen elsewhere. Thus the *Los Angeles Times*, which would not scruple to bracket "socialised medicine" with Communism, has produced recently a benefit plan to provide insurance against costs of doctors' calls for employees and their dependents, the cost of diagnostic X-ray and hospitalisation including surgery. Incidentally some indication of the care of this organisation for its employees may be gathered from the concluding paragraph of the note to employees: " probably as many questions will come to your mind as came to mine. The Personnel department will answer these and will be open until after midnight Tuesday, Wednesday and Thursday for convenience of those working nights. Your usual fine co-operation will be appreciated."

It is significant that the A.M.A. now recognises group practices with prepaid insurance as the " American way," provided of course that they are approved by the State medical societies.

Another factor has recently entered into the development of medical services, and that is the demands of organised labour. Recently the steel-workers struck. They were not asking for more money but for security. The fact that the strike was settled on the lines of Blue Cross hospital cover is worthy of note. The great trade unions are developing tremendous power. Steel-workers', mine-workers', and teamsters' unions now represent a potent force in demanding prepaid medical care. The international garment-makers' union already has a model health scheme.

COMPULSORY INSURANCE ?

At the other extreme to the A.M.A. is the compulsory health insurance favoured by the President and his advisers led by Mr. Oscar Ewing. This aims to provide medical care by taxation. Opposition to this " socialised medicine," as it is called, is growing and is likely to reach its peak during the presidential election year of 1952. The A.M.A., for example, has now burnt its boats and entered openly the political arena. Dr. Fishbein has been replaced by professional lay organisers. In an article on " the Dogged Retreat of the Doctors " which appeared in *Harper's Magazine* last December the following comment was made on the present methods :

> " Instead of trying to deodorize the A.M.A., the new promoters took it out and buried it. One hundred and forty thousand old family physicians arose in its place, all wearing beards, wing collars, high button shoes, and threadbare frock coats, all keeping an all-night vigil at the bedside of your curly-headed little child and mine. KEEP POLITICS OUT OF THIS PICTURE. 'The Doctor' never was a good painting, even in the Tate Gallery tradition. You may have seen it on your doctor's wall when you were young; it used to be distributed as an advertisement for Petrolagar. It made the doctor feel good. If Whitaker & Baxter [the promoters referred to] are right, it still does."

Although many people, lay and medical, deplore the A.M.A.'s entry into this field, there is widespread support for their opposition. The States are jealous of Federal power, and Big Business naturally fears the growth of Socialism.

What is the attitude of the man in the street ? He is truly perplexed. He has to pay very heavily for medical care at a time when the costs of the necessities of life are rising. Railway and transport fares have recently been increased and food costs are rising, including the price of coffee. In Harlem and The Bronx a three-roomed apartment may cost 40 dollars a month and a visit by a physician 4 dollars with another 3 or 4 dollars for the prescription. This represents nearly £3 per visit at the present rate of exchange. On the west coast charges are higher. The first office call may cost 8 to 10 dollars, with 5 dollars for subsequent visits. X-ray and pathological investigations may cost 20–25 dollars extra. A simple doctor's bill may therefore be 40–50 dollars. Obstetrical costs range from 150–1000 dollars, with extra charges in complicated cases. Some idea of the effects of these charges may be gained from the fact that a hotel booking-clerk with a gross salary of 3000 dollars a year had to pay 400 dollars f[illegible]ife's confinement, 200 dollars for the doctor[illegible] dollars for the hospital fee. An accountant developed tuberculosis, and all his savings, 6000 dollars, went in one year. A university graduate student in history had to pay 100 dollars before his infant daughter could be admitted to hospital to be operated on for acute appendicitis. In another instance a patient, already stripped and prepared for operation, had to sign the cheque for the surgeon before he could be taken to the operating-theatre. These are extreme examples, and it is true that voluntary prepaid medical care would have met these charges; but even so most of these schemes take no account of chronic illness. It is the common experience of the Montefiore Hospital in New York that patients with malignant disease have exhausted all the family savings before seeking the benefits of the hospital's home-care service.

The man in the street is therefore in favour of the principle of compulsory insurance. This was made clear time and time again in discussion with newspaper reporters, radio and television announcers, railway employees and the like. On the other hand there would be full agreement with Mr. Micawber when he said " Annual income twenty pounds, annual expenditure nineteen nineteen six, result happiness. Annual income twenty pounds, annual expenditure twenty pound ought and six, result misery." The American citizen knows full well that the addition of medical insurance to the social-security tax may make just that difference to the family budget.

THREE CHOICES

In conclusion it may be said that there are three alternatives facing the people of the United States in this matter. They are :-

1. *The maintenance of the status quo.*—This is an impossibility because of the constant development of prepaid medical-care schemes on a voluntary basis or compulsorily through the demands of organised labour. Attempts to do this would also disregard the heavy financial burden of chronic illness and above all would take no account of the disastrous economic effects of a business depression or slump.

2. *The introduction of a compulsory health service on the British pattern.*—This would be difficult if not impossible on administrative and geographical grounds. An attempt to enforce it would meet the full weight of opposition by the business men, quite apart from the A.M.A. It is doubtful whether the trade unions would be whole-heartedly in support, for their position vis-à-vis the government is very different to that of trade unions in this country. The people themselves are unlikely to welcome such a revolutionary step. It is significant that Mr. Oscar Ewing is now reported as saying that " the British plan is totally unsuited for the U.S. In England the health service is part of a broad programme to reorganise the basic social and economic structure of the country and eight-ninths of the cost comes out of the revenue. This is utterly foreign to the President's proposal which is strictly an insurance plan on a pay-as-you-go basis."

3. *A compromise between voluntary and compulsory health insurance.*—The analogy that would probably appeal most to the American people at the present time would be to say that the choice lies between a cheap motor-car with 100% government insurance, so that the car can be knocked about, or a better car and make the individual user pay the first £5 insurance. On this principle Federal funds would be allocated on a matching or grant-for-grant basis and used by the States to build and equip new hospitals and to improve existing hospitals. State insurance would cover major illnesses and it would be left to the individual to provide his own cover for minor illness.

Developments along these last lines would satisfy nearly everyone and avert the dread of what are considered in the United States to be the basic weaknesses of the English scheme—namely, steeply rising expenditure on social services without individual incentive to save, and the lay and political control, or " socialisation," of medicine.

In England Now

A Running Commentary by Peripatetic Correspondents

MOST of the contributions to In England Now have pith or point or even both. This is merely a despairing cry. Can any learned reader tell me how to stop thoughtless people ringing our front-door bell to inquire about surgery times. Our surgery hours are listed in full view on the gate-post and again on the surgery door, yet day after day people walk past the plate and ring the bell at our private house to ask what they are. I've now got to the stage of taking them by the elbow, steering them to the gate, and showing them the answer to their question in black and white before their very eyes. Can it be that the national eyesight is as bad as the rush for spectacles suggests, or are we fast becoming unable to help ourselves? We have heard a lot lately about the policeman's Blue Lamp. Perhaps a return to the doctors' Red Lamp would be a good thing. All I know is, no maid or receptionist will stand the perpetual and pointless peeling on the bell. The telephone is nearly as bad, but we have a remedy there; we can have it removed. We stopped the door bell only to find the front-door panels were nearly splintered with knocking. Our cry of despair is not the only one. Every other G.P. we know has the same difficulty. Perhaps the Minister would let us charge a shilling for the recreation of ringing the doctor's bell. I shouldn't mind answering it for that. Or has anyone any other ideas?

* * *

As a mere patient, may I ask whether all psychiatrists "doodle" throughout their consultations? I have had treatment for a year by three separate psychiatrists, one in a provincial town and two in London, and all three scribbled, arranged things in patterns, or just doodled the whole time. A favourite trick is to make a pyramid with everything within reach, starting with a penknife, then a pencil, then a fountain-pen, a syringe, a smaller pencil and forceps, right down to india-rubbers and syringe-needles. While this goes on the head is tilted back, the work admired, one eye opens and closes to see it at all angles, while the patient's patience is strained to screaming-point. Then the whole thing is swept over, and off he starts again, often on the same task or on a slight variation of it. Another tilts his chair back as far as it will go, often balancing it on one leg only. There he sways, eyes often closed, while the patient is kept on edge, wondering just when he is going to tip backwards. He may keep this up for an hour and even longer, unless he is in a doodling mood; then he suddenly leaps forward, grabs a pencil, and starts on a pattern on the blotter. This achieved, back goes the chair again.

Is it because they get fed up with hearing our outpourings, or is this a sign that they are absorbed in the case? Anyway, it has at times needed all my self-control not to say: "For goodness sake *do* stop doodling; it's getting on my nerves." But perhaps this is a new test of self-control, and your psychiatric readers will smile at my ignorance.

* * *

No-one expects the producer of a play or film to be omniscient about details when their actors must pretend to be Pasteur or some other notable technocrat. And though I'm often irritated by what I feel must be the producer's carelessness in these matters, I've learnt not to complain when Mr. Paul Muni-Pasteur doesn't sterilise his loop properly after dipping it in anthrax cultures (it's quite possible Pasteur didn't either), lest the family turn on me for destroying their theatrical illusions by nagging about inessentials. I don't complain even when from the battlements of Elsinore I see high jagged peaks in the Danish hinterland. But I ventured a crack the other night in the third act of *Venus Observed*.

Here was a lordly boudoir-cum-observatory, and (centre, back) a domed roof covering a neat little clock-driven equatorial which we had already seen in expert use, before lunch by that admirable and accomplished amateur, the Duke of Altair, on a full-dress eclipse of the sun. Now night has fallen, and I and the rest of the audience are beglamoursed enough by author and actors to withstand a thousand minor implausibilities. In the gloom a window (back, R) is filled with a blue radiance that casts sharp shadows on the sill. Moonlight? Surely not. Just a poetic exaggeration of starlight. When the Duke opens one side of his observatory dome to show the rings of Saturn to his latest love. I am relieved to see only a velvet night sky in what I deduce from the morning's events to be a south-easterly direction. Then in his zodiacal perambulations the Duke opens the dome to the north-east, and lo! the pair are drenched in a bright vertical beam of indubitable moonlight.

Now this isn't an esoteric blunder like Pasteur-Muni's bacteriology. After all, the elements of astronomy are mastered in the third form. Indeed, in another scene of the play they are nicely observed, for the October sun duly sets R, and later dawns L. But I protest that a moon which twelve hours earlier was obliging the drama by obscuring the sun could not possibly have been more than very very new, and had no business to be flaunting herself in the zenith at midnight. Yet neither of the ardent star-gazers was taken aback by this startling vagary. I don't blame the young lady. She had at the time much on her mind, and in any case was unobservant enough to miss the eclipse that morning as she drove through the countryside. But the Duke ought to have known better.

* * *

News from behind the Iron Curtain is often surprising and sometimes incredible. The following item, which reached me a few weeks ago, was sufficiently surprising; but I can testify to the credibility of my informant.

"Our family," ran her letter, "has increased by one small carp, about the size of a sardine, which we found in the stomach of a fish whose English name I do not know any more, but in German is called *Hecht*. My husband was in Slovakia for three days and my brother-in-law caught the big fish there and sent it to us. The fish was dead all night in the train, but next morning, when my cook opened him, to our greatest surprise we found the live little carp in his stomach. The carp is slightly injured; his skin is torn off one side, but he seems quite happy in our bath and is quite a pet with us after his miraculous survival; but I suppose we had better put him into the river which is his natural habitation."

* * *

Letters from America always give me a thrill, even if they only contain shining multicoloured circulars advertising some new therapeutic agent. But when they carry the name of a well-known hospital on the envelope—that of a Medical Mecca in fact—my hand shakes and my pupils dilate with anticipation. Yesterday just such a one arrived, and excitedly I tore open the envelope. "Dear Dr. ——," it said, "We are very anxious to know the words of the well-known rhyme 'Digging up Father's Grave to Lay a Sewer' which I last heard you sing in Brindisi. We wish to use it at the opening of the new Research Building here." Alas; such is fame. Why do we toil and moil as we do? Blood, sweat, and tears poured out in the cause of suffering humanity, and all I am known for in the New World is a Cockney ditty of very doubtful nature. It is my face I am now turning to the wall.

* * *

The practice of otorhinolaryngology in His Majesty's aircraft-carriers, amid a welter of wax-in-ears and sore throats, has its occasional compensations. In one week there were two of these lighter interludes, both in patients complaining of earache and deafness. On auriscopy the first was found to have an external auditory meatus blocked with red and white material which proved on syringeing to be a toffee-paper. The second, a staid *matelot* whose symptoms had developed suddenly during a cinema performance in the after lift-well, presented through the auriscope the fascinating spectacle of a cockroach lying in the classical fœtal posture against the drum. Its difficult delivery was accompanied by more than a little banter.

* * *

Absently I passed a cigarette to the Head of Colin's school, who had honoured us by his presence at tea. "No thank you," said he; "I don't smoke except *incognito*." "Surely you mean *sub rosa*?" said I. "Or possibly," said Margaret, "*ad nauseam*?"

Letters to the Editor

ATOMIC DEFENCE

SIR,—A leading article on Atomic Defence addressed to the medical profession is timely. I have no quarrel with the substance of your extracts from Park's and other articles, but your winged words in the final paragraph will reach a wider audience, amongst the general population, and seem to me to lack your customary wisdom and prudence.

You ask "Will any defence system be able to do more than rescue those at the fringe of the affected area?" You attempt no answer; but there certainly are measures of defence even for those well within the fringe.

There is no doubt in the minds of those who have studied the whole question intensively, that hitherto published estimates of the casualties to be anticipated in our cities are far too high; those estimates should be very substantially reduced.

You go on to allude to the "politicians" who "speak so glibly" of atomic defence. The outstanding politician who has spoken is the Minister most concerned. His remarks were far from "glib"; they were based, I am told, on a brief deriving from the careful and considered appreciation of the situation by the experts of the Services' and Civil Defence Staffs.

No-one who is conversant with the potentialities of modern weapons of war is likely to underestimate the task they would impose on the medical profession. It will include the maintenance of morale, and that may be seriously impaired by incautious phraseology and still more by a suggestion that the most severely stricken victims will be abandoned to their fate without any planned and practised efforts for their relief.

London, W.1. E. ROCK CARLING.

HOSPITAL BEDS

SIR,—With reference to your leading article of Feb. 4, it may interest you to know what has been done at the London Hospital to decrease the number of unoccupied beds.

Before the war, owing to a rigid "firm" and "full duty" system, I regret to say there was never less than 20% empty beds. During the last six months the average number of empty beds has been 7·7% and—if private wards and maternity and staff beds are not included—under 5%. This has been done by having 10 unallotted beds which are used for accommodating a patient when there is no bed available in the appropriate ward for an emergency. What actually happens is that the emergency patient is admitted to the appropriate ward, and a patient from that ward nearing the time of discharge is accommodated in the unallotted bed. In this way an emergency patient, who in the old days would have been refused, is now admitted; and we have proved that with a total number of 650 beds in this building, 10 unallotted beds are sufficient for this purpose.

H. BRIERLEY
House Governor.

The London Hospital, E.1.

CONTROL OF TUBERCULOSIS

SIR,—In more than twenty years' experience of the preventive and therapeutic aspects of tuberculosis, I cannot recall any time when the plight of the tuberculous subject awaiting treatment has been more desperate. This urgent sociomedical problem confronts every general practitioner and physician, and with even greater acuity, every chest physician.

The current interest in the matter evinced in the lay and medical press indicates that complacency must be replaced by action and that 400 deaths per week, mainly among breadwinners, in England and Wales alone, must no longer be condoned.

The problem must be tackled on a national scale and with ruthless drive. Teaching hospitals and regional boards must combine to organise a scheme comparable with the Emergency Medical Service during the war. This is no longer the time to dispute their respective responsibilities. The Ministry of Health should issue a directive for genuine constructive measures to the boards of regional and teaching hospital alike, who, in turn, should indicate to groups of individual hospitals the nature of their duties to the tuberculous patient. In explanation of the long waiting-lists for hospital accommodation the plea of insufficient beds is invariably proffered, but a greater regard for accuracy reveals that the hospitals of the country contain many unoccupied —because unmanned—beds. The first problem remains, therefore, to increase the nursing and auxiliary staff. With this object in view, it should be made widely known that providing those who nurse the tuberculous subject in suitable wards are Mantoux-positive reactors, the incidence of the disease is not significantly greater than in comparable groups of the general population.

In order to increase nursing staff each hospital group should allocate some of the nurses in training in its area to an institution—whether sanatorium, general hospital, or erstwhile isolation hospital caring for the tuberculous —as part of the general curriculum. Unrestricted use should be made of part-time and assistant nurses, ward orderlies, and even partly trained personnel on the model of the V.A.D. and Red Cross and St. John. Rehabilitated tuberculous patients and ex-patients might also, following vocational guidance, contribute to overcoming the present emergency.

Only in this way lies hope of reducing the waiting-lists —lists that are rarely less than six months and often extend to a year and even eighteen months where surgery is required. Even an acute medical emergency such as hæmoptysis—if it is known by hospital authorities to be due to tuberculosis—may receive little more consideration. Is the victim of this disease, even in 1950, to remain a "social leper"?

The risks of procrastination are threefold: to the patient, whose condition becomes exacerbated; to his family, who are exposed to a serious risk of infection; and to the public health. One has only to compare the facilities open to sufferers from other diseases—and even they are not perfect—with the barriers raised against the admission of tuberculous patients.

If every hospital group were compelled to allocate about 10% of its beds to tuberculosis during the present emergency, the waiting-lists could be controlled and the disease would, within measureable time, cease to be a blot on our social escutcheon.

Finally, a plea for the integration of preventive and therapeutic aspects under one authority, where prevention and rehabilitation also receive due attention, for without such unification all efforts to control the disease will be brought to nought.

PHILIP ELLMAN.

London, W.1.

SIR,—Like Dr. D. G. Morgan, who wrote last week, I was interested in your leading article of Feb. 4. Dr. Morgan, indicated "more fruitful lines of inquiry which could reduce 'bed wastage' in these days of 'bed famine'," and in particular suggested that more clinical investigations could be carried out on outpatients.

With this I am in hearty agreement, and those of us who have been driven to treating and investigating tuberculous patients in their own homes will subscribe to his view that the "increase in diagnostic facilities would release a large number of beds urgently required for the patients needing treatment that can only be provided in a hospital."

In my view, however, a very much more radical attempt should be made to allocate existing hospital beds in a manner proportionate to the importance of the diseases which they are to serve. It is well known that the allocation of beds to tuberculous patients falls far short of the number that they would receive were such a principle acted upon.

The number of patients on the waiting-lists for British sanatoria has increased since 1944 from 4000 to nearly 10,000, whilst at the same time the number of beds available for treatment of this disease has not changed significantly. Notification figures are rising; and as the *Times* stated in a leading article on Jan. 18:

> "Tuberculosis is killing 400 people each week in England and Wales and unhappily the majority are in the productive years of their lives. If a catastrophic epidemic of some other disorder produced comparable figures urgent action would surely be taken. . . . A bold measure—and boldness is required—would be to allot wards for tuberculous patients in the general hospitals. . . . To-day all hospitals are part of the Health Service and as such could be given instructions to take the necessary measures. . . . Action is urgently needed."

It has been shown in a number of general hospitals that, provided wards are set aside for tuberculous patients, there is little danger to the nursing staff or other patients. In fact, as has been stated by Dr. Horace Joules (*Times*, Jan. 25), at the Central Middlesex Hospital the morbidity-rate amongst nurses is lower than in any of the hospitals investigated by the Prophit trust.

This is an example of enlightened and progressive preventive medicine, but it is accepted in by no means all areas. In an adjacent London borough one board of governors controls all the 862 general-hospital beds available for the sick of that area. It is typical of the general attitude to tuberculosis that only 8 of these beds are allocated for the treatment of this disease. Dr. Toussaint (who also wrote last week) draws attention to the perpetuation of the low status of the tuberculosis service; and here is another sign of the apathy towards, or perhaps deliberate disregard of, the major problem facing British medicine by the Ministry responsible for the health of the community. It is time that our National Health Service faced up to its national problems.

TREATMENT OF LEPROSY

SIR,—The leading article in your issue of Jan. 28, which contained my article on diamino-diphenyl sulphone in the treatment of leprosy, is very interesting and informative, but it contains one or two statements which call for comment.

You say: "With a remedy so inexpensive and apparently so effective, leprosy may be the first of the great infectious diseases to be brought under control largely by chemotherapy." Surely this sentence needs some explanation and modification? For another major infectious disease, syphilis, we have long had chemotherapeutic agents which appear more effective than anything we have, or are likely to have, in leprosy. Has syphilis been brought under control? Possibly its incidence, and certainly its severity, have been reduced, but the disease is still common.

I have long been of the opinion that without a reasonably effective remedy, which so far we have not had, leprosy control was in many countries an impossible task. Sulphone treatment is a step in the right direction, and more rapidly effective treatments may be evolved. But the chemotherapy of leprosy, although it may reduce the incidence and the severity of the disease, is never likely to eradicate it.

One further point—this time on chaulmoogra oil. You speak of "the direct antibacterial action" of the oil and say that "intravenous injection of its derivatives is followed by disintegration of leprosy bacilli." Very few experienced workers will accept that statement.

In a previous leading article,[1] you pointed out that the evidence of chaulmoogra preparations being bacteriolytic is not strong, and that their effect may be due to counterirritation and stimulation of tissue response. The administration, by injection or otherwise, of many different medicaments has been reported to cause clinical improvement and changes in the morphology of the bacilli. Apparent changes in morphology can also be produced by many other factors, including variations in staining technique.

It is perhaps worthy of note that sodium hydnocarpate, the preparation reported to produce disintegration of bacilli, has never been widely used or advocated by experienced workers. Rogers and Muir[2] state that "it is considered less beneficial than the oil or its esters": Muir, in his recent book,[3] does not even mention it: and Cochrane[4] mentions it only to say: "It is our belief that these remedies [sodium salts of fatty acids of hydnocarpus (chaulmoogra) oil] are not effective in the treatment of leprosy."

Uzuakoli, Nigeria.

JOHN LOWE.

EXFOLIATIVE DERMATITIS COMPLICATING STREPTOMYCIN THERAPY

SIR,—We thank Dr. Sumner (Feb. 4) for his interest in our article of Jan. 21 and for his pointer to the similarity to his own cases.[5] Frankly, we think that this similarity is very superficial, but it does enable us to compare what we think are two entirely different entities. In our view, these two conditions have in common only one factor—they both arose during the administration of streptomycin.

Dr. Sumner's three cases all occurred after long periods of streptomycin, and the skin lesions were of the types met with in vitamin-B deficiency. We were struck by the constant involvement of the perineum. When the skin elsewhere was involved, the involvement was never generalised; in one case the disorder was described as seborrhœic dermatitis, and in another as a dry scaling eruption over a "glove-and-stocking" distribution. The tongue appears to have been involved in all these cases and the description is of the picture usually seen in vitamin-B deficiency. These features, together with the improvement following the exhibition of vitamin-B complex, leave little doubt as to the factor involved in the syndrome.

Our case, on the other hand, developed early in the course of treatment (9th day). The skin eruption was the condition we primarily described, and we are sure that Dr. Sumner will agree that it was different from the manifestations he noted. The picture was of dermatitis passing through all the recognised phases to exfoliation and finally denudation. More important, although we described a severe stomatitis, at no stage was mention made of the tongue and this did not show the distinctive features seen by Dr. Sumner. Finally, there was the rise in temperature, which we regard as of great significance but which was presumably absent in Dr. Sumner's cases as no mention was made of fever.

We maintain that this is an entirely different picture and is anaphylactic in origin. In case 2 of Dr. Sumner's series, an erythematous rash occurred over the forehead and wrists after 5 days' streptomycin, but this rapidly disappeared. This surely is the rash, in its mildest form, which we have attempted to describe? Dr. Sumner tells of further cases he has had, but states that he does not include the common skin eruptions; and he maintains that these do not even warrant consideration of the advisability of continuing with the drug. It is here that

TREATMENT OF RHEUMATOID ARTHRITIS

SIR,—For over two years I have been treating cases of rheumatoid arthritis with intravenous injections of procaine. I decided to try also Lewin and Wassén's new method[1] of using ascorbic acid and deoxycortone acetate, with a view to comparing the results.

In each of three cases where the new treatment was given, there was a sense of well-being which continued after the injection for the rest of the day, and a slight decrease of pain. With procaine there is a sense of well-being, pronounced decrease of pain, and an increase in the range of movement of the affected joints. The injections have to be repeated daily at first, but as the condition improves they are gradually cut down to about one every ten days; if treatment is stopped, relapse ensues. Each injection is of 1% procaine (without adrenaline) 5–10 ml. according to the individual's tolerance. I find that this gives far better results, and I have seen no ill effects except for transient light-headedness after the injections.

Kasr-El-Ainy Hospital, Cairo. S. M. TALAAT.

MOTION-SICKNESS AND ANTI-HISTAMINES

SIR,—The *effectiveness* of the antihistaminic drug β-dimethyl-aminoethyl benzohydryl ether 8-chlorotheophyllinate ('Dramamine') in motion-sickness was described by Gay and Carliner[2] and Rust and Fosbery.[3] As this drug is a relatively weak antihistaminic agent[2] and its ether base is known to have relatively little specificity toward histamine, the question arises whether its effect in motion-sickness is due to histamine antagonism or to another factor.

Recently on a voyage across the North Atlantic, on which dramamine was not available, we tried giving daily 0·025–0·05 g. N-dimethylamino-methylethyl-dibenzoparathiazine (3277 R.P.; 'Phenergan') prophylactically as well as for treatment of motion-sickness. This drug is a highly active anti-histamine with long-lasting action.[4] In almost every case we saw good results. One case was especially impressive.

A woman suffering usually from motion-sickness even on land vehicles, and showing no improvement after administration of 0·6 mg. hyoscine, was completely relieved after receiving a combination of 0·6 mg. hyoscine with 0·025 g. phenergan. As phenergan caused considerable drowsiness, we tried combining 0·6 mg. hyoscine with 0·02 g. phenobarbitone, but this combination had no more effect than hyoscine alone. Placebos and occupational therapy were without effect. Prophylactically phenergan was effective alone.

These are, of course, merely a few observations, which might suggest that further, more exact, investigations with several specific antihistaminic drugs should be carried out. As to the mode of action, it should be noted that Rosenthal and Minard[5] and Kwiatkowski[6] have already suggested the action of histamine on sensory nerves, while Ambrus, Ambrus, and Jacob[7] have shown that specific histamine desensitisation (tachyphylaxia) causes analgesia in rats.

THE RH HAPTEN

SIR,—In a recent annotation[1] you expressed the hope that those who had been trying to repeat Carter's work on the extraction of the Rh hapten from human erythrocytes would state their findings.

We have followed both Carter's original method and her modified method, using erythrocytes from a single donor and also pooled erythrocytes from a number of donors. In all cases Rh-negative cells were extracted at the same time as Rh-positive ones and used as a control. Particular care was taken to adhere closely to all the details of the technique described.

Extracts had a very slight inhibitory effect on Rh antisera, but extracts from Rh-negative cells proved equally inhibitory and it was concluded that the phenomenon was of a non-specific character. In no case was any specific inhibitory effect observed.

F. STRATTON

RESISTANCE TO THE TUBERCLE BACILLUS

SIR,—Dr. Sutherland (Feb. 4) appears to take a somewhat peculiar view. Let us, he seems to say, study the question of immunity and resistance; let us forget (for the moment, at least) the tubercle bacillus.

The relative importance of seed and soil may provide a fascinating ground for discussion, but meanwhile people die daily who need not die.

The Prophit report did indeed say what Dr. Galen said in A.D. 80. In the intervening years it is surprising that so little notice has been taken of his remark. Surely, if it was made extremely difficult for anyone to come into contact with a tuberculous patient, fewer people would contract the disease.

In America they have tackled the problem of bovine tuberculosis on these lines. In 1918 the campaign to destroy all tuberculous cattle was launched. Today the disease is rarely seen. In this country, where doubtless the subject will provide interesting matter for discussion in the years ahead, over 2000 children die and nearly 4000 are crippled yearly by the disease. Mass X-ray examination, good training and hygiene, as at Papworth, adequate provision of beds, and B.C.G. inoculation surely provide major lines of attack on this terrible scourge.

Such effective action would, incidentally, do something to make the present National Health scheme more worthy of its name and less of a salvage and cure service.

Farnham Royal, Bucks. M. E. M. HERFORD.

POSTOPERATIVE PARALYSIS IN THE UPPER EXTREMITY

SIR,—The mechanical difficulties of supporting a patient in the steep Trendelenburg position during prolonged operative procedures have been well illustrated by recent correspondence.

Attention has been focused principally on special supports for more or less prominent anatomical features, such as the shoulders and hips. I would like to draw attention to the effect of friction. The usual covering for operating-tables consists of a 'Sorbo' rubber mattress with a smooth skin of rubber encasing it. The whole is loosely attached in some way or other to the polished metal surface of the table. The total effect is somewhat similar to that of placing a loaded toboggan on the slopes of the Cresta run. If the rubber cushioning can be firmly fixed to the table surface, and its upper surface —i.e., that in contact with the patient—is given some form of non-skid finish, the friction effect produced might well prevent 50% of the patient's weight from falling on whatever other form of support is used. I am assuming, of course, that the skin of the patient's back

---

1. *Lancet*, 1949, ii, 1141.

is allowed to come directly in contact with the rubber. It appears to me that a combination of the usual right-angled flexion of the legs with this form of cushioning would do away with the necessity for any dangerous pressure applied to the shoulders or iliac crests.

I am in contact with manufacturers, in order to obtain a rubber mattress of the suggested design.

MEDICAL TEACHING IN BAGDAD

SIR,—Your note last week (p. 284) refers to the Iraqi government's desire to enlist British doctors to teach in the Royal College of Medicine in Bagdad. As I held the chair of physiology there for five years before the war a word on my experience may be of interest. I entirely enjoyed my stay in Iraq, in both the professional and the social aspects, and it was with regret that I relinquished the appointment for family reasons. The opportunities for research are unrivalled and the college authorities and Directorate of Health gave me every facility I needed for investigation. Moreover the research problems there in parasitology, infectious diseases, and nutrition (to name only three fields) urgently demand solution and one has a splendid chance to contribute to the struggle against human suffering.

I would have no hesitation in recommending any doctor to apply for one of these posts if he accepted one condition. That is that he would be prepared to develop to the full social contacts with the Iraqi people. If he only wishes to mix with other Britons he had better stay at home. Both my wife and I found our many Iraqi friends pleasant hosts and welcome guests. High government officials assured me that they considered British participation in Iraqi social life to be an important contribution to the development of the country. Personally I found it well worth while.

The opportunities for sport are good and the climate is not so trying as some people make out, though the winter is rather cold.

London.

W. P. KENNEDY.

VITAMIN B_{12} AND THYROID FUNCTION

SIR,—The effect of liver extracts on thyroid function is obscure. Wintrobe[1] has suggested that they may have a thyrogenic action because of the not-infrequent development of hyperthyroidism in patients receiving liver therapy for pernicious anæmia.

On the other hand, it has been shown[2] that some of the toxic effects of thyroid extract in rats can be prevented by feeding with liver, and it is also stated that patients receiving thyroid therapy for hypothyroidism require larger doses of thyroid extract if liver therapy for pernicious anæmia is initiated.[3] It is, moreover, suggested that there is in liver extract a component, probably vitamin B_{12} itself, which has a specific antithyroid action.[3]

If the latter statement were to be substantiated, it would obviously be of prime importance, not only to those interested in the possibility of a new drug for the treatment of hyperthyroidism, but also to patients with addisonian anæmia, to whom high doses of vitamin B_{12} will undoubtedly be given now that it is cheap and freely available, and in whom symptoms of hypothyroidism might occur. Such an effect of prolonged administration of vitamin B_{12} has not, as far as we know, been reported yet by workers in this country or in the U.S.A.

We felt, therefore, that it would be of interest to assay the possible antithyroid activity of vitamin B_{12} by the method of Stanley and Astwood,[4] using radioactive iodine—a technique recently used by us to assess the antithyroid activity of *para*-aminobenzoic acid.[5]

Two male patients with normal thyroid function were given 60 µg. and 100 µg. respectively of crystalline vitamin B_{12} ('Cytamen,' Glaxo) at a time when iodine accumulation in the thyroid gland was proceeding at a steady rate. The samples were from a batch which had been proved clinically to be active in pernicious anæmia. The administration of the drug did not have, in either patient, the slightest effect on the straight line of the graph which is obtained when the thyroid-gland activity is plotted against the square-root of the time. If the drug, in the dosage used, had had any antithyroid activity, an immediate effect on iodine retention in the gland would have been shown by a downward deviation of the graph from the straight line. We have no experience of the effect which would be obtained if a drug with definite thyrogenic properties were assayed by this technique. We should, however, expect that an upward deviation of the curve would occur, corresponding to an increased iodine absorption by the gland.

We concluded that in a dosage of 100 µg. or less, vitamin B_{12} has no significant effect on thyroid function.

THE CHEST PHYSICIAN

SIR,—Young chest physicians like myself will be grateful that Dr. Toussaint has exposed, in his letter last week, the dilemma in which we now find ourselves. Should we clear out of the specialty if it is to have no decent future ?

I became interested in tuberculosis when I began to discover what a wide range of unexplored fields of medicine this disease offers. Tuberculosis occupies a unique position, with ramifications not only into many branches of medicine and surgery, but into aspects of sociology, psychology, business, economics, politics (certainly local politics !), and indeed every aspect of human affairs. I became increasingly fascinated by the possibilities of tuberculosis control and felt impelled to specialise in this branch of medicine. It appeared that no longer were young men like myself to be penalised financially for displaying interest in that one major disease which par excellence is disregarded in teaching hospitals. My interest in tuberculosis is clinical as well as social ; I do not aspire to an administrative appointment divorced from clinical medicine such as used to be a reason for a young man interesting himself in the disease.

And now what ? Has a mistake been made ? Is tuberculosis after all not to recruit its share of the ablest in my generation ? If we are foolish enough to interest ourselves in this work, must we then accept the consequences of a lower income on account of our strange idiosyncrasy ? Is the degradation of the tuberculosis service to be perpetuated ? The situation is ludicrous. Glasgow has a higher mortality from this disease than Hamburg despite conditions there in the last decade ; while Scandinavia can afford to inquire politely why we do not take steps to prevent a preventable disease.

The tragedy of all this is not the personal fate of doctors who happen to be interested in tuberculosis, but the personal fate of the four hundred British men and women who die each week of this disease—which is more preventable than any other great scourge of mankind today.

The taxpayer wants to see his diseases effectively controlled as quickly as possible at minimal expense. Three administrative measures, all supported by those who really understand tuberculosis, could immediately be taken and in ten years would reduce the tuberculosis problem by more than half : (1) recruit the best brains of the profession into the tuberculosis field by offering we wish to bring him to task. We think that our case, although a rare one, was sufficiently important to warrant a little consideration for these trivial anaphylactic rashes which appear early in streptomycin therapy.

---

1. *Lancet*, 1949, ii, 1141.

months, as that of the control sample of the same batch which had not been subjected to the process. The remaining two samples—those chloroformed four and five times—showed an appreciable loss of potency compared with the control.

While the purification of vaccine lymph by phenol is certainly very simple and satisfactory, that by the passage of chloroform vapour has the advantage of being much quicker while being equally efficacious and harmless. This process seems to have been first described by Green,[3] who has presented convincing experimental evidence of its suitability; and in India at least three institutes manufacturing vaccine lymph have adopted this method for routine purification.

Vaccine Institute, Belgaum, Bombay. R. SANJIVA RAO.

"IMPROVERS" OF FLOUR

SIR,—The decision of the authorities to discontinue the use of nitrogen trichloride ('Agene') in flour,[4] after the Medical Research Council had recognised its serious and often fatal effects on animals, is to be welcomed.

It is difficult to understand, however, why it should have been necessary to replace this "improver" by another chlorine compound—chlorine dioxide—which is in my opinion unnecessary, and will, furthermore, cost vital dollars since it will have to be obtained from the U.S.A. "Improvers" are *not* necessary to safeguard baking qualities. They are merely artificial means to speed up the natural maturing of flour, at the same time bleaching it and giving a whiter-*looking* loaf.

It is regrettable that in the popular belief whiteness in bread should be synonymous with purity. In fact, the very opposite is the case. To my mind, bread should contain nothing but pure unadulterated wheat flour. In the case of other foodstuffs, such as milk and butter, the addition of chemicals is already forbidden by law. Why not in the case of the "staff of life"—bread?

West Wickham, Cambridgeshire. C. P. ALLINSON.

DEOXYCORTONE ACETATE AND LYMPHADENOPATHIES

SIR,—In connection with the numerous recent articles in your journal on the surprising effects on rheumatoid arthritis of 'Cortisone,' adrenocorticotropic hormone (A.C.T.H.), and deoxycortone acetate together with ascorbic acid, I wish to call attention to one application of the adrenal-cortex steroid hormones in the field of the lymphopathies.

I found that the administration of large doses (20–50 mg. per day) of deoxycortone acetate ('Cortivis' Vister) has a moderate, transient, and inconstant effect on Hodgkin's disease and on lymphatic and myeloid leukæmia.[5] This action is not augmented by the simultaneous administration of ascorbic acid. Similar results have now been reported by Pearson, Eliel, and Talbot using A.C.T.H.[6]

On the other hand, I have observed sensational and permanent relief in a rare disorder—giant follicular lymphadenopathy (Brill-Symmers disease). In hyperplastic lymphopathies of other histological types I have also observed very good results, with complete and permanent disappearance of enlargement of lymph-nodes and spleen. These observations, recorded briefly last year,[5] have lately been described more fully.[7]

Medical Clinic,
University of Palermo, Sicily. G. FRADÁ.

INFANTILE PYLORIC STENOSIS

SIR,—Mr. Ward-McQuaid and Dr. Porritt, in their article of Feb. 4, describe a method of medical treatment which shows a failure-rate of about 40%. (The exact figure cannot be stated as "the numbers treated medically . . . could not be accurately estimated"). With medical treatment such results usually end in the abandonment of the method altogether and operation on all cases from the beginning.

In my opinion better results can be obtained with medical treatment by: (1) selecting suitable cases, (2) four-hourly feeding, (3) gross reduction of feed-volume (1–$1^1/_2$ oz. per feed in the first 24 hours, and increasing slowly up to full feeds), and (4) large doses of atropine methylnitrate from the beginning. The authors give gr. $^1/_{750}$ before each feed, whereas I give gr. $^1/_{100}$ before three feeds in 24 hours, reducing this to two doses at about the 5th day. This large dose can be given conveniently in lamels made by Savory & Moore, in which gr. $^1/_{100}$ is contained in $^1/_4$ sq. cm. As these lamels are cut from sheets marked in squares of 1 sq. cm., care must be taken that only $^1/_4$ of a marked square is used at each dose. In the past five years I have treated 61 selected cases by this method. There were 2 failures (3·3%) and no deaths.

With regard to surgical treatment, Mr. Ward-McQuaid and Dr. Porritt, and also Professor Smellie in his letter of Feb. 11, emphasise the importance of complete preoperative hydration as a means of reducing mortality. There is another side to this argument, and Professor Smellie hints at it when he warns against the danger of overadministration of sodium chloride. Personally I prefer Mr. David Levi's technique for Rammstedt's operation, in which there is no need for preoperative hydration, and which incidentally shortens the period in hospital by about 24 hours. In five years I have thus treated 58 cases with 1 death (1·7%). Combining medical and surgical treatment, there are 119 cases with a mortality-rate of 0·8%.

I would say that nowadays a number of people achieve very low mortality-rates using very different techniques. What seems common to all of them is a full understanding of the disease in general and their own method of treatment in particular.

Tunbridge Wells. N. M. JACOBY.

SIR,—No child has died who has been operated upon for pyloric stenosis at the Westminster Children's Hospital (formerly the Infants' Hospital, Vincent Square) since 1947, when this hospital was reopened. My personal figures have lately been published.[1]

I should like to emphasise the importance of ensuring that these infants are treated by a trained pædiatric team and that they are not operated on by the duty surgeon of the day unless he has had specialised pædiatric experience.

London, W.1. DAVID LEVI.

SIR,—A series of more than 100 cases of congenital pyloric stenosis has been treated by Rammstedt's operation in the Leeds General Infirmary since February, 1947, with a mortality of less than 1%: 96 cases were operated on consecutively without a death.

The pædiatrician makes the diagnosis within a few hours of seeing the infant, and unless there is some associated disease or dehydration he asks for early operation. The anæsthetist is an artist with open ether, shuns ethyl chloride, and is careful that the trickle of oxygen inside the mask does not become a blast to blow up the stomach. The surgeon is merely the craftsman in the team. No special instruments of any kind are used; a rectus-split incision is made high so that the fair terms comparable with other specialties[1]; (2) unify the broken and divided organisation of tuberculosis control by setting up regional joint panels[2]; and (3) open the doors of general hospitals to tuberculous patients.[3]

TUBERCULOMEN.

FLATULENCE IN INFANCY

SIR,—May I make some remarks on Dr. Tanner's letter of Feb. 4?

A baby's stomach differs from that of an adult in that when empty of food it does not collapse but contains air. Some babies can get rid of this easily whilst taking a feed. Some babies reach a stage of "block" like Dr. Tanner describes. I think, however, it is a dangerous doctrine to advise *all* mothers to "burp" babies two to three times during the feed. Some do better without any "burp" at all. I have had a mother of a baby who got rid of its air easily and silently, tell me that "She could not get him to break wind though she had been told she had got to." It is also a dangerous doctrine because in some mothers the break in feeding arrests the flow of milk.

Are we sure when mothers consult us about their baby's "wind" that they are all referring to the same thing? In my experience quite 80% of these complaints refer to the "drawing up of the baby's knees" when it cries. As this is a reflex depending on the action of crying, it is not indicative of anything. To attribute it to "wind" is a grandmother's tradition.

York. F. CHARLOTTE NAISH.

SIR,—I should like to endorse the views of Dr. Tanner and also to emphasise a point in your annotation of Feb. 4.

The family kittens, suckling half-upright, seemed conspicuously wind-free, and postprandial percussion on their bulging abdomens produced a dull note.

Having had considerable trouble with the wind of our experimental eldest, his three subsequent controls were always fed upright on my lap. Inclined in the arm, they have complete support, while support all the way up my back, as in the nursing-chairs our grandmothers used, ensured complete comfort to both parties. And the results were remarkable. Burps were automatic, and outwith my control.

I have also fed them in this position when stirring the sauce, herding their seniors, answering the telephone, or proceeding in a fast car round corners, with never a care. It certainly has much to recommend it.

Edinburgh. CONSTANCE KUENSSBERG.

SOCIAL SIGNIFICANCE OF SYMPTOMS

SIR,—I read with interest Dr. Gooddy's article last week. The growing tendency of the socially inadequate to exploit their grievances against society is in itself a symptom of what J. L. Halliday calls a sick society.

In the past, such people could more easily resign themselves to suffering in the present life as they had some religious faith which promised them happiness hereafter; the same beliefs rendered their luckier contemporaries tolerant of the human suffering around them. Nowadays, the "have-nots" want their heaven here and now, and the "haves," whose capacity for rationalisation of their guilt-feelings stops short at humanitarianism, cannot so well withstand their bullying. The fears and frustrations of the modern world intensify these problems.

The Welfare State has been erected as a human substitute for Providence, and the same irrational claims and expectations are therefore directed towards it: it is regarded as an omnipotent ever-loving parent of whom all citizens are the favoured children. Unfortunately, each child wants the lion's share, and as the Welfare State more and more rules out competition by achievement, the method of competition by nuisance-value is correspondingly encouraged.

In the end, inevitably, the Welfare State collapses or becomes, in self-defence, the Totalitarian State: that is, the people in power act repressively in order to prevent the State being as it were devoured from within. Nature, and human nature, know nothing of an equalitarian society.

London, W.1. F. R. C. CASSON.

PURIFICATION OF VACCINE LYMPH

SIR,—McClean[1] has drawn attention to the suitability of phenol as an agent for purifying vaccine lymph. This method of purification has been in use at the vaccine and antitoxin laboratory, Jamaica Plains, Boston, Mass., for several years.

In this institute, trials were made by adding phenol in a concentration of 0·5% to the diluent—a 50% solution of glycerin in water. Even with simple storage of the phenolised vaccine lymph at −11°C, the bacterial count dropped to 8000 per ml. in one month and to 900 per ml. in two months. As a result of the treatment with 0·5% phenol, no deterioration in potency was noticed. Butler's[2] claim that the phenolised virus was more thermostable than the untreated virus could not, however, be confirmed. Purification by the passage of chloroform vapour has stood the test of time and experience in this institute. None of the drawbacks experienced by McClean has ever been encountered. The vaccine lymph is purified by the process in half an hour, the bacterial count usually being reduced to about 1000 per ml. or less.

From experience, satisfactory results by the "chloroform process" appear to depend on the following factors: (1) the dilution of vaccine lymph during the process; (2) the distribution of vaccine lymph during the process; (3) the total amount of chloroform used; (4) the air-pressure employed; and (5) the time taken for the process.

It is well known that purification by this method is effected by the chloroform that actually goes into solution, the best results being obtained when the solution is saturated. When chloroform vapour is bubbled through vaccine lymph, some of it goes into solution while the rest escapes. It is thus clear that saturation-point can be reached much earlier and with a smaller quantity of chloroform when the bulk of vaccine lymph is distributed into several large-size test-tubes connected in series, so that the chloroform escaping from the first test-tube is led through all the remaining test-tubes in succession.

Satisfactory results are obtained in this institute with vaccine lymph distributed in quantities of about 40 ml. in test-tubes measuring 8 in. by $1^{1}/_{4}$ in. The requisite pressure is maintained by a 'Presso-Vac' pump, and about 13 ml. of chloroform is consumed during the whole process, which lasts half an hour. These different factors may have to be adjusted to suit local conditions. With precautions regarding the temperatures during the passage of chloroform vapour and during subsequent aeration for three hours, no adverse effects on the potency have been noted. A batch of vaccine lymph was "chloroformed" five times, a portion being taken out after each exposure. These five sets chloroformed from once up to five times were tested for potency. The potency of three of these samples chloroformed once, twice, and three times remained the same, over a period of six

Births and Deaths Registration Acts, 1874–1926. The traditional common-law test of a live birth is that the baby utters a cry; no evidence on this point is reported in the Oldham case. Under the strict law every live birth, however short the life, must be registered; the obligation to register is of course, imposed upon a series of persons concerned, beginning (in ordinary cases) with the parents, but attaching to anyone present at the birth. The 28-week rule cannot apply to live births. It applies only to the fœtus born with no sign of life; in that case registration is unnecessary. If the fœtus is born dead *after* 28 weeks, it must be registered as a stillbirth.

Obituary

ROBERT PATTON RANKEN LYLE

B.A., M.D. DUBL., M.D., D.CH. DURH., F.R.C.O.G.

Dr. Ranken Lyle, emeritus professor of midwifery in the University of Durham, who died on Feb. 1, had a powerful and attractive personality. Born at Coleraine nearly 80 years ago, he qualified at Trinity College, Dublin, in 1894. He was assistant master at the Rotunda before he was appointed, in 1899, lecturer in midwifery and diseases of women at the medical school of the University of Durham.

[Baron

From his first arrival he was in charge of the Maternity Hospital in Newcastle, but there was no department of gynæcology at that time: the general surgeons and physicians considered that they could supply the needs of the subject. Dr. Lyle, at his own expense, opened the Samaritan Free Dispensary for Women at the very gates of the Royal Victoria Infirmary, where he did many operations and gave free advice. Shortly afterwards he was appointed gynæcologist to the infirmary, and when he retired in 1930 he was appointed consulting gynæcologist. In 1908 he had been appointed to the chair of midwifery and gynæcology in the University of Durham, and he held this post until 1935 when he was appointed emeritus professor. Two years later the honorary degree of doctor of surgery was conferred on him.

The Newcastle Maternity Hospital at the beginning of the century had only 15 beds, which Professor Lyle held to be quite inadequate provision for the area. He therefore equipped a large industrial school as a modern maternity hospital of 90 beds, which was opened by the Princess Royal in 1923 and which is known as the Princess Mary Maternity Hospital. At the same time he bought and equipped a large house as a maternity home for women of moderate means. He backed both projects financially until they were well established and finally self-supporting.

E. F. M. writes: "As an operator Lyle was gentle and simple in his technique. He rarely used an abdominal retractor even during deep pelvic operations. In his teaching he was firmly opposed to the earlier beliefs that retroversion of the uterus caused backache, and ridiculed those operations for fixation or suspension of the uterus which were so commonly done elsewhere. In his clinical teaching he stressed the importance of examining a case from above down, and not from below up—namely, to study the human being before examining her pelvic organs in detail. In all his dealings with his colleagues he was the soul of generosity and good humour. He was popular, indeed loved by his students, and a prize in clinical midwifery is called after him."

For a number of years Professor Lyle was a justice of the peace to the city of Newcastle. His main hobbies were stamp-collecting and shooting. He leaves a widow and one daughter.

WILLIAM DREWETT ARNISON

M.A., M.D. DURH.

Dr. Arnison, who died on Jan. 28 two days after his 85th birthday, was born in Allendale Town, a country village in the south-west corner of Northumberland. His father, grandfather, and great-grandfather had all been surgeons in Allendale, and one of his uncles was professor of surgery in the University of Durham.

He spent his boyhood in his native village, till in 1878 he was sent to Durham School, from which he later went on to the old College of Medicine at Newcastle upon Tyne. Of his early days at the college he has left an interesting account in the *History of the Newcastle School of Medicine*, which he helped to prepare at the time of the school's centenary. Having graduated M.B. in 1886, he came up to London to take the Conjoint qualification, and for a couple of years he acted as house-surgeon to the West Herts Infirmary at Hemel Hempstead, but then returned to the North, where he spent the rest of his professional life. Soon after going into general practice, he became one of the medical officers to the Post Office, an appointment which he held for many years.

His career as an anæsthetist started in 1891, when he was appointed to the staff of the Royal Victoria Infirmary. Here he did sterling work for fifteen strenuous years, during which he was the one recognised specialist in anæsthetics in the town and district. Always an advocate of ether administered with a Clover inhaler, he became expert in the use of that apparatus. In those days an anæsthetist at the Newcastle Infirmary had no light task, for he might be called upon every day for work in the theatre from 9 A.M. till 2 P.M., and there were many long lists at that time; but Arnison was most punctilious in his attendance and in the performance of his duties. He was always interested in the patients and always made an examination as to their fitness before undertaking the anæsthetic. For those days his records were unusually accurate and his large experience was carefully recorded and annotated. A painstaking teacher, he set a high standard in the care of the patient, and his work was amply recognised by his seniors and colleagues. It gave him immense pleasure when a few months ago he was elected a fellow of the Faculty of Anæsthetists of the Royal College of Surgeons.

In 1907, to the surprise of many, he gave up his post as anæsthetist to take charge of what was then called the electrical department at the infirmary. To begin with, there was practically nothing in the department—a room in the basement rather like a cellar and some primitive apparatus represented the whole outfit. But with the devoted help of Dodds, formerly a plumber employed at the infirmary, Arnison built up a department which during the 1914–18 war did an enormous amount of work, both for the infirmary and the large military hospital in the adjacent Armstrong College. When the department was finally handed over to a successor in 1925 it was a well-established going concern.

After retiring from the staff of the infirmary with the title of consultant radiologist he continued as a member of the house-committee and chairman of the drug and instruments committee, bringing mature experience, common sense, and absolute integrity to the problems involved. For years he was also a regular attender at Convocation and he was later appointed a member of the senate of Durham University. It gave him great pleasure when he was awarded the honorary degree of M.A.

Arnison was always a great influence for good in the spheres in which he moved. His sterling characteristics were deeply appreciated by his associates and his ideals were an outstanding example to the juniors with whom he liked to associate. At the infirmary he always leaned to the clinical side of the work, and for years he acted as chairman of the Surgical Aid Society which had been started by his uncle, William Christopher Arnison. A man of culture, he loved books and he had himself a useful library. He was fond of history, especially military history, but poetry was always his first love. He was also much interested in his home county and its history, and he often took part in the excursions arranged by the Antiquarian Society, of which he was an enthusiastic member.

Dr. Arnison, who married rather late in life, is survived by two daughters.

G. G. T.

liver is the only viscus visible when the peritoneum is opened; the hæmostat which is used to lift up the stomach is also used to split the pyloric tumour after the outer layer has been incised. It is considered that interrupted subcutaneous sutures of twisted silk are desirable in the final closure of the wound.

The infants are not segregated; all cases are operated on after associated diseases like otitis media, stomatitis, and umbilical sepsis have been treated. The average stay in hospital is 2–3 days and our aim is to make this period 24 hours: the fatal case had been in hospital 10 days before the diagnosis was made.

All of us treating cases of congenital pyloric stenosis wish to emulate the remarkable series of Ladd et al.[1] (a series anæsthetised by a nurse giving open ether), and until we can give an efficient biochemical study to any ill infant we shall not be able to compete.

Leeds. H. S. SHUCKSMITH.

Medicine and the Law

Electroconvulsive Therapy and Fractured Femur

AT the recent Worcestershire assizes Mr. Justice Hallett dismissed an action in which a patient claimed damages for pain suffered, and incapacity caused, through alleged negligence in his treatment.

It was common ground between the parties that the patient, a man, having been for some time before in a neurotic condition, was advised to undergo electroconvulsive therapy in hospital; that the first treatment took place on April 29, 1947, and the second on May 20; and that he subsequently complained of pain and, under advice, went on June 19 as an inpatient to the hospital, where it was discovered that the neck of the left femur was broken. An operation was performed in an orthopædic hospital. The patient's left leg is now $1^1/_2$ in. shorter than the right and there is limitation of movement.

The plaintiff's case was not that the fracture was due to negligence but that the medical superintendent and another doctor at the hospital were negligent in having been so slow in diagnosing the fracture, and that his two family doctors were negligent in that they never diagnosed it. In his opening speech, plaintiff's counsel stated that it was well known in the medical profession that a fracture was a risk in electroconvulsive therapy, because the treatment caused violent contraction of the muscles, and the powerful muscles of the thigh, in contracting, created greater danger for the femur than for any other bone; the danger increased with the age of the patient; the patient was 59. The surgeon who had performed the osteotomy, called for the plaintiff, said that if the operation had been performed one month earlier, there was no guarantee that it would have had any better result. Fracture of the femur during electroconvulsive therapy was very rare, and in the absence of any history of accident, an impacted fracture was not infrequently missed.

When the defendants' case was opened, the medical superintendent stated in his evidence that he made no clinical examination of the patient's leg, because this was not his patient. A member of the medical staff said he had carried out electroconvulsive therapy between 7000 and 10,000 times and had never before seen it cause a fracture of the femur. The patient's reaction after the treatment on May 20 was normal; he himself received no complaint and therefore made no examination.

Mr. Robert Davies-Colley, consulting surgeon to Guy's Hospital, called on behalf of the defendants, did not agree that it was common knowledge that a fractured femur might occur during this treatment; he thought that he himself might quite easily have failed to detect the fracture; muscular rupture would have been the most likely cause of any pain. Defendants' counsel called five male nurses from the hospital; their evidence was that, after the treatment on May 20, the patient did not complain of pain in his leg.

In delivering judgment, Mr. Justice Hallett found himself unable to rely upon the evidence of the plaintiff, whose mental health had caused trouble for some time. The judge entirely exonerated the defendant doctors. They had not been guilty of negligence. Even if there had been a finding against them in that respect, the plaintiff would have had the greatest difficulty in establishing a right to damages; he would have had to show that the alleged delay in diagnosis caused delay in treating him, whereas it was probable that the surgeon would have delayed the osteotomy until the patient's mental condition had settled down.

The judge dismissed the claim with costs, though it is possible that little of the expense of defending the action will in fact be recovered. Fortunately for themselves, all four of the defendant doctors had safeguarded themselves: they were members of the Medical Protection Society.

Duty to Register Premature Births

The evidence at an inquest held at Oldham on Feb. 1 on the body of a prematurely born child disclosed some uncertainty about the legal obligation to notify such births. There was said to be a hospital rule that the birth of a baby under 28 weeks should not be notified, whether it was born alive or dead. This birth was not in fact notified, the hospital superintendent apparently deeming that there was no sign of life. By some astonishing accident the body, sent to the hospital incinerator, was found five days later on the municipal rubbish-heap. The case was brought to the coroner's notice. It could, of course, have raised suspicion of a criminal concealment of birth. He directed an inquest and, in the evidence summarised below, the jury (in the course of determining the cause of death) found that the child had lived for 24 hours.

Dr. G. B. Manning told the coroner's court that he thought the baby was a 26–29 weeks' child and had lived for at least 6 hours. The nurse who delivered the child in the Boundary Park Hospital at Oldham said it was born alive; she placed it in the oxygen tent and kept it under observation till she went off duty at 8 A.M. It was then alive and its condition was quite good for its size. Resuming duty at 8 P.M., she found it still alive but the condition had deteriorated; she thought it died the next morning. She baptised the child; asked by the coroner why she did so, she replied "because I am a Roman Catholic." She did not fill in any notification form; it was not usual to do so in the case of a child under 28 weeks; that was the rule or custom of the hospital, whether the child was born dead or alive. Dr. John James, doing duty as locum tenens at the hospital, said that he went with a nurse to see the baby; he made some remark about putting its weight on the notification form and was told of the rule that babies under 28 weeks were not notified. He queried the existence of the rule; it was confirmed by the hospital superintendent. The latter, in his evidence at the inquest, testified that he had seen a fœtus without a name; he saw no sign of life or breathing in the ordinary meaning of the word; it was not to be regarded as a live birth; the appearance of breathing might have been given by the high pressure in the oxygen tent.

This case is not unique. The relevant statutes, as was explained in these columns three years ago,[1] are the

Royal College of Obstetricians and Gynæcologists

On Tuesday, March 21, at 5 P.M., at the college, 58, Queen Anne Street, London, W.1, Dr. Arthur T. Hertig, professor of pathology at the Boston Lying-in Hospital, will deliver the first John Shields Fairbairn lecture. He is to speak on Hydatidiform Mole and Chorionepithelioma.

British Institute of Radiology

The institute is considering the possibility of reviving or starting new branches in areas of the country not already covered by existing ones. Members are invited to write to the honorary medical secretary at 32, Welbeck Street, London, W.1, expressing any views they may have in this matter.

Institute of Sociology

At a meeting of the institute to be held at Burlington House, Piccadilly, London, W.1, on Tuesday, Feb. 28, at 5.30 P.M., Prof. W. J. Rose will open a discussion on Antagonism to Strangers—Theory and Fact. Further particulars may be had from J. L. Peterson, Esq., University House, Victoria Park Square, E.2.

The Nation's Manufactured Foods

The nutrition panel of the Food Group (Society of Chemical Industry) is holding the fourth of its meetings on this subject on Wednesday, March 22, at 6.15 P.M. at Burlington House, Piccadilly, London, W.1, when the use of jams and other spreads as foods will be discussed.

International Congress of Pædiatrics

The sixth International Congress of Pædiatrics will take place in Zurich at the end of July, under the presidency of Prof. G. Fanconi. Plenary sessions will be held on July 24 and 28. Lectures and exhibitions will also be held from July 21 to July 30. Registration date has been postponed to April 22, and further particulars may be had from the American Express Co.

Mental Health within the Family and the School

Today, Friday, Feb. 17, at 5 P.M., at 1, Wimpole Street, London, W.1, the British standing committee for the World Federation for Mental Health is holding an international symposium on this topic. Prof. J. M. Mackintosh will be in the chair, and the speakers will include Dr. A. Répond (Switzerland), Prof. W. Line (Canada), Prof. H. C. Rumke (Holland), and Dr. J. R. Rees. Tickets may be had from the National Association for Mental Health, 39, Queen Anne Street, W.1.

St. John and Red Cross Hospital Library

An exhibition to show the work of this department is being held in London from Feb. 8 to 18. The exhibits include the first English-made automatic page-turner. So far the 49 automatic page-turners and 15 microfilm projectors lent to British hospitals through the library are American and were given to the Red Cross. The library sends books to 1850 Service and civilian hospitals in England, Wales, and Northern Ireland, and 67 Service hospitals overseas. Over 4000 voluntary workers give their time to it, and last year 98,000 gifts of magazines and 93,000 gifts of books were sent to hospitals from the library's headquarters alone. There is a special loan service for tuberculosis patients, a special request service, and a foreign loan library, in addition to the general service. Volunteers are given instruction in hospital librarianship.

Constitution of N.H.S. Tribunal

The National Health Service (Amendment) Act, 1949, provided for a wider choice of the professional member who serves on the disciplinary tribunal, and the Minister of Health has, after consultation with the organisations representative of the professions concerned, appointed panels from which the practitioner member of the tribunal is to be selected for each case. The members of the panel of medical practitioners are: Dr. H. G. Dain, Dr. A. E. Jenkins, Dr. C. F. R Killick, Dr. A. Talbot Rogers, Dr. A. S. Wilson, and Dr. S. A. Winstanley. The members of the panel dealing with the supplementary ophthalmic services are: Mr. J. S. Arkle, Dr. Dorothy Campbell, Dr. R. R. Garden, Mr. R. Affleck Greeves, Dr. T. G. W. Parry, and Mr. A. McK. Reid. The address of the clerk to the tribunal is 2, John Adam Street, Adelphi, London, W.C.2 (Temple Bar 6055).

Institute of Laryngology and Otology

Nine lectures on pharmacology as applied to otorhinolaryngology will be given by Dr. C. A. Keele at the institute, 330, Gray's Inn Road, London, W.C.1, beginning on Feb. 27. Particulars may be had from the dean.

Nurses in Northern Ireland

The statutory restriction in Northern Ireland on the use of the title "nurse" will come into effect on March 16. After that date nursing agencies must also be duly licensed by the ministry of health and local government.

Royal Appointment

Surgeon Captain A. W. McRorie has been appointed an honorary physician to the King from Nov. 12, 1949, in place of Surgeon Captain J. F. M. Campbell, who has been placed on the retired list.

A Service Reunion

The C.M.F./M.E.F. Physicians reunion dinner will be held on Saturday, April 1, at Simpson's-in-the-Strand. Those interested should apply to Dr. Arthur Willcox, 66, Harley Street, London, W.1.

Claims to Sickness Benefit

In England and Wales new claims under the National Insurance Act during the weeks ended Jan. 3, 10, 17, 24, and 31 were as follows: 150,900, 169,500, 150,600, 142,700, 160,800. During this month the weekly average was 154,900. The weekly averages in the twelve months from January to December, 1949, were as follows: 157,900, 179,800, 185,200, 114,400, 97,700, 83,500, 78,600, 88,800, 100,900, 119,100, 136,200, and 96,700.

Nomenclature of Pest-control Products

The British Standards Institution has appointed a technical committee "to prepare standards for the nomenclature for insecticidal and fungicidal chemicals and other pest control products." This committee, whose chairman is Mr. H. J. Jones, includes representatives of Commonwealth countries, Government departments, scientific societies, and manufacturers' organisations.

Institute of Social Psychiatry

On March 22, at 2 P.M., at Seymour Hall, Seymour Place, London, W.1, the institute is holding a conference on Day Hospitals and Social Rehabilitation. The speakers will include Dr. Noel Harris, Dr. Joshua Bierer, Dr. E. B. Strauss, Dr. Donald Blair, Dr. Doris Odlum, and Dr. Desmond O'Neill. Tickets may be had from the institute, 9, Fellows Road, N.W.3.

Maida Vale Hospital for Nervous Diseases

Some of the war damage to this hospital has now been repaired, and facilities for neurosurgery are once again available. The department of electro-encephalography has also lately been reopened, and the pathological services have been greatly extended. Postgraduate teaching is given at the medical school for candidates preparing for higher examinations, and there are also clinical demonstrations for practitioners in the North West metropolitan region.

Remuneration of Medical Civil Servants

Last year a joint committee formed by the British Medical Association, the Ministry of Health Medical Staff Association, and the Institution of Professional Civil Servants drew up a proposed scale to align medical salaries in the Civil Service with those in the National Health Service (see *Lancet*, Jan. 14, p. 75). At the Ministry of Health the chief medical officer's salary would be increased from £3000 to £5000, and in certain other grades the maximum would be augmented by close on £2000. This claim has now been rejected by the Treasury.

Foreign Scholarships

The British Council has been asked to find candidates among British students for scholarships which are being offered for 1950–51 by the following countries: Belgium, Brazil, Czechoslovakia, Denmark, Finland, France, Germany (Universities of Cologne and Munster), Italy, the Netherlands, Norway, Persia (University of Teheran), Sweden, and Switzerland. The closing date for applications is March 10, and details of the scholarships may be had from the controller, education division, British Council, 3, Hanover Street, London, W.1.

Notes and News

PROTECTION FOR THE MIDWIFE

A RECENT case when heavy damages were awarded against a midwife as a result of bottle burns to a patient, has led the council of the Royal College of Midwives to provide safeguards for all full members of the college by including third-party indemnity as a privilege of membership. The cover provides up to £5000 damages and legal expenses against accidents or injury to mother or baby in the course of the midwife's professional duties whether she is acting as a midwife or maternity nurse, also liability in respect of accidental direct damage to property caused by, or through, the negligence of the midwife. In cases of citation before the Central Midwives Board legal expenses up to £25 are provided.

WEIGHTS IN EARLY CHILDHOOD

LAST year Gore and Palmer[1] pointed out that with infants the use of "average weight for age" as an index of general health had the disadvantage that normally there was a very wide dispersion; and they suggested that a chart might be designed to show the actual mean weights and standard deviations in normal infants. Acting on this suggestion, Glaxo Laboratories Ltd. have produced a chart based on the figures reported by Gore and Palmer for normal London infants in 1947. The chart shows the upper and lower limits of weight for boys and for girls from the age of four weeks up to five years; and means and standard deviations are set out in tabular form at the side. The chart may be obtained on request by public-health departments, hospitals, and other institutions concerned with child welfare.

RESULTS OF LEUCOTOMY

IT is appropriate that the first number of *Anais Portugueses de Psiquiatria,* which began publication last October, should contain a review of the results in 100 cases of leucotomy; for we owe this form of treatment to Egas Moniz, of Lisbon. In the opinion of the authors (Barahona, Polónio, and Sousa) the chief indication for leucotomy is the failure of conservative measures, including insulin therapy and electroconvulsive shock. With the proviso that conservative treatment should be tried first, the earlier leucotomy is done the better are the results. The reason for this delay is that when the results of insulin therapy or of electroconvulsive shock are beneficial they are better than those of leucotomy. These workers have never observed after insulin or electroconvulsions such deterioration of personality as sometimes follows leucotomy. They conclude that leucotomy has no specific action on mental disease and does not alter the association of ideas and the structure of the patient's psychosis, but that it changes the emotional manifestations thereof. They consider that leucotomy weakens the patient's purposiveness, steadiness, foresight, awareness of self and of others, integration of personality, aggressiveness, and mental activity, the patient becoming more of a robot responding to external stimuli.

MEDICAL FEES AND THE POLICE

A Home Office circular to police authorities lays down the following principles for the payment of doctors' fees:

Emergency treatment.—Where a doctor gives emergency treatment, whether or not at the request of the police, to someone injured in a road accident in which a motor vehicle is involved, the doctor is entitled to a fee in accordance with the Road Traffic Act, 1934. In other cases of accident or sudden illness in the street, the doctor may claim a fee from the local executive council; but if the doctor is not in the health service, the police may pay the fee and if possible recover the cost from the patient. These arrangements apply also where a doctor is called to a police station to treat someone who is neither in police custody nor the victim of an offence.

Persons in police custody.—Where a doctor is called to treat, or to examine for police purposes, a person detained in custody, the doctor should be paid out of the police fund.

Victims of an offence.—The police may pay a fee for the examination of such victims, and also for their treatment provided that no fee for emergency treatment has been claimed from the local executive council.

Drunkenness or other offences.—Where a doctor is called by the police to examine someone charged with drunkenness or any other offence, or in cases where such a charge may be made, the doctor is to be paid out of the police fund. If the person being examined wishes to call his own health service doctor, he should be informed that such attendance is not part of this doctor's obligations under the health service and that a fee may thus be payable by him.

Dead bodies.—If a doctor is called to treat a seriously ill person who dies before he arrives, an emergency fee will be payable by the local executive council (unless the person was on the doctor's list). If, however, the doctor is summoned after the person's death, payment will be made out of the police fund.

In a few areas, the local executive council have arranged with the doctors in the National Health Service that no fee shall be claimed for emergency treatment; and the capitation fee is correspondingly higher. The arrangements described above apply also to these doctors, whether or not they claim a specific fee from the executive council. The payments out of the police fund which have been described will not be made to those police medical officers who are engaged at an inclusive salary.

PROFESSIONAL TRENDS

THE *Manchester Guardian* lately sent a questionary to some 1500 medical professors and lecturers throughout the United Kingdom to find out how many read their journal and to obtain other information of interest to advertisers. Almost half replied, and there were only three real dissentients. One sent back a blank form, another a form torn into small pieces, while a third returned the form with the somewhat ambiguous statement "Barmy" scrawled at the foot.

An analysis of the replies showed that 54·4% of the respondents were readers of the *Manchester Guardian* (15·7% regularly, 38·7% occasionally), while 77% bought two or more newspapers daily. "Only 6%" owned a television set, though another 6% intend to buy a set during the coming year ("provided I can persuade my wife" one admits). Many of the negative replies to this question included such heartfelt comments as "God forbid," "Never!", or "I see enough already!" Some 37% read classified advertisements, while 38% consciously read display advertisements. Of the group, 87% owned a car, and 13% had two or more cars. Priority had enabled many of the professors, &c., to buy new cars, and more than 60% had post-war models. One reported ownership of a 1919 model, but pending a sight of this the *Manchester Guardian* statistician suspects a clerical error.

University of Liverpool

At a recent examination for the D.T.M. & H. the following were successful:

A. Deuchars, Muriel M. D'Souza, R. D. Eagland, K. G. Koshi, C. M. Norman-Williams, S. L. H. Smith, W. G. Timmis.

Dr. R. D. Eagland has been recommended for the Milne medal and for the Warrington Yorke medal.

University of Birmingham

The title of reader in obstetrics and gynæcology has been conferred on Dr. H. C. McLaren, lecturer and first assistant in the department of obstetrics and gynæcology. Dr. B. MacMahon has been appointed research fellow in social medicine. Mr. J. M. Small has been appointed clinical lecturer in neurosurgery, and Mr. O. T. Mansfield in plastic surgery.

Royal College of Physicians of Edinburgh

At a meeting of the college held on Feb. 7, with Sir David Henderson, the president, in the chair, the following were elected to the fellowship:

Alexander Brown, Robert A. K. Harper, R. Brockie Hunter.

The following were elected to the membership:

E. R. Gauld, I. R. Gray, W. T. Strauss, E. S. Thodey, J. A. C. Wilson, Jagat Ram, W. P. Small, N. R. Grist, L. G. Leitch, W. R. M. Alexander, J. B. Wilson, P. F. Bartley, W. J. H. Lord, D. B. Nathan, Thomas Joyce, A. A. B. Swan, K. J. Keeley, Jessie E. J. Grainger, C. H. M. Walker.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty held on Feb. 6, with Dr. W. R. Snodgrass, the president, in the chair, the following were admitted fellows of faculty: John Hewitt *qua* surgeon, and Stuart Ian Alexander Laidlaw *qua* physician.

Royal College of Surgeons of England

At a meeting of the council held on Feb. 9, with Sir Cecil Wakeley, the president, in the chair, the Hallett prize was awarded to Harold Ellis of the University of Oxford. Diplomas of membership and diplomas in public health and in psychological medicine were granted to those named in the report of the comitia of the Royal College of Physicians in our issue of Feb. 4 (p. 237).

On Feb. 7 the council of the college dined with the master, wardens, and court of the Barbers' Company at Tallow Chandlers' Hall, when they received from their colleagues of old time a replica of the silver-gilt grace cup given to the Company of Barber-Surgeons by King Henry VIII in 1540.

THE BODY-IMAGE IN NEUROLOGY*

MACDONALD CRITCHLEY
M.D. Brist., F.R.C.P.
SENIOR NEUROLOGIST TO KING'S COLLEGE HOSPITAL, LONDON;
PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN SQUARE;
DEAN OF THE INSTITUTE OF NEUROLOGY

ONLY within the last two decades have neurological phenomena been related to the body-image and its disorders. Even today we perhaps utilise this conception too little. The subject forms a fascinating chapter in neuropsychiatry, conspicuous by the high quality of some of the contributions.

The expression body-image (body-scheme; *image de soi*) refers to the mental idea which an individual possesses as to his own body and its physical and æsthetic attributes. It is often taught that Head and Holmes (1911–12) first drew attention to the idea of a body-image, when they wrote:

> "The final product of the tests for the appreciation of posture or passive movement rises into consciousness as a measured postural change. For this combined standard against which all subsequent changes of posture are measured before they enter consciousness, we propose the word 'schema.' By means of perpetual alterations in position we are always building up a postural model of ourselves which constantly changes. Every new posture or movement is recorded on this plastic schema . . ."

The story can be traced to earlier sources however. As an offset to Janet's conception of "psychic tension or potential," Wernicke and his pupils Foerster (1903) and Storch (1902) were calling attention to the importance of some purely physical components which they termed the "somatopsyche" or the "myopsychic factors." Even earlier French psychiatrists had loosely employed the word "cœnæsthesia" to refer to the sum-total of sensations arising from without and within the body. Disorders of this faculty had been spoken of as *délires cénésthesiques* (Raymond and Janet) or *cénésthesiopathia* (Deny and Camus 1905). Comar (1901) spoke of an "auto-representation of the organism." Most important of these earlier contributors, however, was Bonnier, who from 1893 had been studying various aspects of cœnæsthesia. These found maturity when he applied the term "aschematia" to the disorder by which certain aspects of ourselves cease to function in the notion that we have of our own body" (Bonnier 1905). Other variants of this condition he called "hyposchematia," "hyperschematia," and "paraschematia." Most of Bonnier's clinical examples were cases of vertigo.

Following the attention focused on this subject by Head and Holmes, many papers appeared, most of them dealing with the question of phantom limbs after amputations. In 1923 came Schilder's first contribution to the whole problem. His work *Das Körperschema* was expanded in 1935 to appear as *The Image and Appearance of the Human Body*. This forms a sort of *chef d'œuvre manqué* which just falls short of being one of the great monographs of neurology. The year before, van Bogaert had published his important paper which dealt with the *image de soi* particularly from the anatomical side. Lhermitte's major contribution appeared in 1939, written in an inimitable style, encyclopædic, yet vivid and arresting. Since that date there has been no outstanding review of the subject, though a number of papers dealing with parietal symptomatology, with the agnosias and with phantom limbs, refer more or less to the body-image.

NATURE OF THE BODY-IMAGE

Many factors contribute to the formation of the body-image under normal conditions. Chief among them are visual factors, tactile impulses, and proprioceptive stimuli. Head and Holmes were especially concerned with the last-named, and indeed their term was "a postural model" of the body. Some authors (e.g., Pirisi 1949) have argued that Head and Holmes's postural model is not the same entity as that known nowadays as the body-image; and indeed these two authors went on to describe another schema or model upon which cutaneous stimuli are localised upon the surface of the body. Though all three factors—visual, tactile, postural—play a rôle, none is essential. That is to say, a body-image of a sort exists in the absence of any one of the foregoing factors. Thus, the blind have their own kind of body-image, as also have those where the stream of tactile impulses, or of postural messages, is interrupted.

These three cardinal factors which, operating together, play so important a part in constituting the body-image cannot however be regarded as the only responsible agencies. One can exclude the operation of all three and yet a body-image can remain. Thus a man may lose his arm and be left with a short stump at the shoulder. There is no longer any limb to be seen, and afferent impulses—proprioceptive and exteroceptive—no longer ascend from the periphery. And yet a phantom sensation remains and keeps up the original idea of integrity of the body-image. This phantom limb, present in the vast majority of all amputees, shows how resistant the body-image is to the effects of mutilation. So firmly rooted is it that it may even require a cortical ablation (or an intercurrent hemiparesis) to cause it to disappear.

Visual Factors.—Ordinarily the conception of one's body-image is to some extent made up from the information gained by inspection. This applies particularly to exposed parts of the anatomy—e.g., the hands. Other regions are invisible except in a mirror—e.g., the face and fore parts of the body. Yet other regions are out of sight even with the aid of a single mirror (posterior parts of the head and torso), though interested women may examine themselves by means of a series of reflecting surfaces. But, at the best, a mirrored image affords information which is neither adequate nor exact. There is, to begin with, no right-left reversal. Self-scrutiny in a looking-glass imposes a certain artificiality, and one is apt to lose the natural animation, the mimic play, and even the tic-like grimacing which may be so obvious to others. The optical component of the body-image is therefore a distorted schema in which the hands are predominant, with the face occupying a secondary and subordinate rôle. But we must not make the mistake of identifying the visual component of the body-scheme with the sensory homunculus of the postcentral gyrus.

In the blind, and especially those who have lost their sight early in life, an optical component is in abeyance and is compensated by tactile and postural hypersensitiveness. The major difficulty in the blind, however, lies in an altered relation between what one may term personal space (i.e., the body-image) and extrapersonal space. The latter is much more constricted in the blind, though auditory stimuli have the property of altering immediately the notions of the blinded man as to distance.

How far visual components are concerned in the eventual state of the body-image has been strikingly demonstrated by the well-known experiments of Stratton (1896), Wooster (1923), and Scholl (1926). Stratton covered his left eye and put in front of the right one a system of lenses which turned everything upside down and from one side to the other. This apparatus was worn constantly for eight days. At first Stratton felt nauseated and giddy: everything was topsy-turvy and his voluntary movements were grotesquely incoordinate. Gradually this improved and by the eighth day a marked

Society of Analytical Psychology

The address of this society is now 25, Park Crescent, London, W.1 (Langham 6108).

Dr. Dagmar Wilson, of Oxford, left early this month for Ceylon, where she will undertake an investigation on the incidence of endemic goitre under the auspices of the World Health Organization, at the request of the Ceylon government.

The Egyptian government has invited Dr. W. R. Aykroyd, director of the nutrition division of the Food and Agriculture Organization, and Dr. F. W. Clements, chief of the W.H.O. nutrition section, to visit Egypt to study their nutrition policy.

CORRIGENDUM: *Medical Films.*—Last week (p. 285) we reviewed a film on the basilar artery produced by the physiology department of St. Bartholomew's Hospital Medical College and the Wellcome Film Unit. We are informed that this does not show the distal end of the basilar artery; and in the experiment which we described the contralateral vertebral artery, and not the contralateral axillary artery, was occluded.

Births, Marriages, and Deaths

BIRTHS

ARMSTRONG.—On Feb. 8, the wife of Dr. T. G. Armstrong—a daughter.

BARRETT.—On Feb. 6, at Bushey, Herts, the wife of Dr. G. M. Barrett—a son.

BOAN.—On Feb. 5, at Tidworth, the wife of Major S. Boan, R.A.M.C.—a son.

BREWERTON.—On Feb. 5, at Watford, the wife of Dr. R. Brewerton—a son.

FLETCHER.—On Feb. 8, in Manchester, the wife of Dr. Frank Fletcher—a son.

HARROLD.—On Feb. 7, in London, the wife of Dr. A. J. Harrold—a son.

HISCOCKS.—On Feb. 7, the wife of Dr. H. F. Hiscocks—a son.

HULME.—On Jan. 19, at Liskeard, the wife of Dr. H. K. Hulme—a daughter.

KOPELMAN.—On Feb. 8, in London, the wife of Dr. Harry Kopelman—a son.

MANN.—On Feb. 3, in London, the wife of Dr. W. N. Mann—a daughter.

MORGAN.—On Feb. 6, at Edenbridge, the wife of Dr. C. R. Morgan—a daughter.

PAGE.—On Feb. 11, in London, the wife of Dr. Francis Page—a daughter.

PLUMMER.—On Feb. 9, at Ilkley, the wife of Dr. T. R. Plummer—a son.

POCOCK.—On Feb. 10, at Clifton, Bristol, the wife of Mr. John A. Pocock, F.R.C.S.—a son.

ROWLATT.—On Feb. 5, at Rochford, the wife of Dr. Basil Rowlatt—a son.

SHEMILT.—On Feb. 9, at Kettering, Northants, the wife of Dr. Peter Shemilt—a son.

n London, the wife of Mr. E. R. Smith, F.R.C.S.

. 8, at Calgary, Alberta, Canada, the wife of
chan—a son.

TAYLOR.—On Jan. 27, in London, the wife of Dr. Stephen Taylor—a son.

WARRACK.—On Feb. 9, at Aldershot, the wife of Lieut.-Colonel A. J. N. Warrack, M.B.E., R.A.M.C.—a son.

MARRIAGES

FAIRLEY—ORR.—On Feb. 11, in London, Barrie Fairley, M.B., to Jean Orr, S.R.N.

FRANKENBERG—COERT VAN TRICHT.—On Feb. 14, in London, John Frankenberg, M.R.C.O.G., to Mieke Coert van Tricht.

GODLOVE—SMYTH.—On Feb. 4, at Lancs,
Leslie Michael Godlove, M.B., to

WILLIAMS—BURDETT.—On Jan. 27, Geoffrey
Williams, M.B., to Elizabeth Bos

DEATHS

CLOUGH.—On Feb. 6, at Whitchurch, Salop, Alfred Hollier Clough, M.R.C.S.

CURTIS.—On Feb. 4, at Naivasha, Kenya, Percy James Curtis, M.R.C.S.

FRAZER-NASH.—On Feb. 8, at Kingston Hill, Surrey, Lilias Frazer-Nash, L.R.C.P.E., aged 90.

HART.—On Feb. 7, at Derby, Arthur Edward Hart, B.A., M.B. Camb., aged 84.

HOSFORD.—On Jan. 28, Thomas Henry Hosford, L.R.C.P.E., aged 82.

JACKSON.—On Feb. 6, at Chadderton, Robert Ashton Jackson, M.B. Manc., D.P.H., aged 63.

PATCH.—On Feb. 4, at Chichester, Burnet Graham Patch, M.R.C.S., lieut.-colonel, R.A.M.C. retd, aged 74.

RODGER.—On Feb. 7, at Dundee, John Rodger, O.B.E., M.C., M.B. Edin., D.T.M. & H., colonel, I.M.S. retd.

STANGER.—On Feb. 8, Geoffrey Stanger, B.A., B.M. Oxfd.

TAUNTON.—On Feb. 8, in London, Richard Eustace Maxwell Taunton, M.B. Edin.

Diary of the Week

FEB. 19 TO 25

Monday, 20th

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Mr. A. Dickson Wright: Surgical Aspects of Hyperpiesia. (First Lettsomian lecture.)

Tuesday, 21st

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. J. E. Piercy: Factors Contributing to Safety in Surgery of the Thyroid. (Hunterian lecture.)

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. R. M. B. MacKenna: Lichen Planus and Lichenoid Eruptions.

Wednesday, 22nd

WESTMI , Horseferry Road, S.W.1
5.30 -theatre.) Clinicopathological
Infection in a Case of Bacterial

NORTH I SOCIETY
8.15 P.M. (Prince of Wales's General Hospital, N.15.) Dr. Harold Waller: Breast-feeding.

Thursday, 23rd

UNIVERSITY OF LONDON
4.45 P.M. (University College, Gower Street, W.C.1.) Mr. Tudor Jones: Peptide Bond in Biochemistry. (First of three lectures.)
5.30 P.M. (King's College of Household and Social Science, Campden Hill, W.8.) Dr. Keith Simpson: Murder.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Sir Paul Mallinson: Psychiatry lecture-demonstration.

Friday, 24th

MAIDA VALE HOSPITAL MEDICAL SCHOOL, W.9
5 P.M. Dr. Anthony Feiling: Neurological demonstration.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASE
8 P.M. (11, Chandos Street, W.1.) Prof. S. P. Bedson, F.R.S.: Virus Infections and Venereal Disease.

Saturday, 25th

BRITISH ASSOCIATION OF
11.30 A.M. (1, Wimpol
NOON Dr. Vera B. Wa t the
St. Louis Confere lergy.
2 P.M. Prof. R. J. Mc lergy.
2.45 P.M. Dr. Brian Ru rmis.

Appointments

ARTHUR, H. R., M.B. Lond., consultant
ologi ospital.
D.M. , Inverness

amb.: junior registrar (casualty officer), St. Andrew's Hospital, London.

BREMER, CONRAD, M.D. Leeds, M.R.C.P.: consultant physician (assistant), Sunderland hospital group.

BRENNAN, E. B., M.B.E., M.B. Camb., D.M.R.: consultant radiologist, Lincoln, Grantham, and Boston hospitals.

CAMPBELL : asst. administrative
M.O.,

FELL, W. : director of physical
medic bridge (from Sept. 1,

Lond., D.A.: consultant anæsthetist, Grimsby
ral Hospital.

., M.R.C.P., D.C.H.: consultant pædiatrician,
tal group.

JONES, D. H., M.B.E., M.R.C.S., D.P.M.: asst. psychiatrist (S.H.M.O. grade), Pen-y-Val Hospital, Abergavenny.

LÉCUTIER, M. A., M.B., M.SC. Leeds: consultant pathologist, Chesterfield Royal Hospital.

LOGAN, KATHLEEN, M.B. Aberd.: junior registrar (anæsthetist) St. Andrew's Hospital, London.

MACKENZIE, IAN, M.B. Lond.: consultant pathologist, Derbyshire Royal Infirmary.

MILLIGAN, W. L., M.D., B.SC. Glasg.: consultant psychiatrist, St. George's Hospital, Morpeth.

QUINLAN, J. T., M.B. N.U.I., D.C.P.: consultant pathologist, Wrexham hospital group.

RAE, J. W., M.D. Edin., M.R.C.P.: asst. physician, Inverness hospitals.

ROSS, R. M., M.B. Edin., D.P.H.: asst. county M.O., Lincolnshire, and M.O.H., Grantham and West Kesteven rural district.

SHARP, C. L. E. H., M.R.C.S., D.P.H.: asst. county M.O., Gloucestershire.

THOMAS, G. O., M.D. Lpool: consultant chest physician, Merionethshire and Montgomeryshire.

TILLOTSON, J. E., M.D. Glasg.: asst. tuberculosis officer, Inverness-shire, and asst. physician-superintendent, Culduthel I.D. Hospital, Inverness.

VASEY, R. H., M.D. Durh., M.R.C.P., D.OBST. R.C.O.G.: senior consultant physician, Sunderland hospital group.

WHEELER, H. Q. O., L.R.C.P.I., D.A.: consultant anæsthetist, Hexham General Hospital and Hexham War Memorial Hospital.

WILSON, A. R., M.C., M.B. Edin., M.R.C.P.: asst. physician, Inverness hospitals.

WOOD, J. C., M.B. Glasg., D.M.R.: asst. radiologist, Inverness hospitals.

To these tactile and proprioceptive means of enhancement, we can add a number of practices whereby the visual components of the body-image are elaborated.

Clothing has already been mentioned in this connection. The mere utilitarian properties of protection are obviously transcended when one considers adornments which are grotesque or outlandish in size. A woman's morale is said to be buoyed up by her hat, especially when it is new, conspicuous, or flagrantly costly. During the German occupation of France, Parisian women reacted against authority by displaying themselves with headgear even more conspicuous in size and colouring than usual. We are reminded of the fantastic head-dresses, not only of certain primitives (Zulus) but also at the French vaudeville. Accentuation of the body-image is also brought about by such practices as the painting of toe-nails, the wearing of anklets, tattooing, sun-tanning—practices which transcend the more decorative functions of make-up, such as coloured finger-nails and ear-rings, which can at least be admired by all and sundry. Whatever the motives for artificial deformations among savages—e.g., piercing the nostrils with spikes, and inserting wooden discs within the lobes of the ears or in the lips—such practices cannot fail to influence deeply the body-image. The same may be said of the custom of wearing masks, especially of gigantesque nature, in ritual, plays, or processions. We see the same aggrandisation of the body-image among the stilt-walkers in American processions.

PHYSIOLOGICAL MODIFICATIONS OF THE BODY-IMAGE

Certain regions of the body-image assume particular importance under varying physiological circumstances. Thus the sphincters possess a highly significant rôle, and according to Schilder they are felt not at the actual aperture but 1–2 cm. deeper. To the victim of diarrhœa the sphincter ani is obtrusive. The sensation of a full bladder causes an enhancement somewhere near the root of the penis in the male, and at a deeper region in the female. Hunger causes the epigastric area to assume importance; thirst focuses attention upon the sides of the tongue and the palate. Sexual excitement promotes the perineum in males, but in females the body-image is concentrated on a region deeper within the pelvis.

The cult of nudism is an interesting psychopathological anomaly with many aspects. One of them at least is associated with a kind of cutaneous hyperschematia. We see this well illustrated in Raoul Faure's novel on the Lady Godiva theme.

Feelings of cold and of heat also enhance the body-image. Alcoholic excess commonly produces complex cephalic sensations, ordinarily spoken of as a “ fat head.” As one person put it . . . “ with a few drinks, my eyelids close and my head seems to be enormously enlarged.” Something similar may be the result of physical duress. Thus Spencer Chapman, struggling alone through the tropical forest, ill with malaria and very hungry, wrote: “ Surprisingly enough I was not at all exhausted, but I felt curiously light-headed—as if the top of my skull were a foot higher than normal ” (Chapman 1949). Even simple embarrassment may cause the victim to feel “ all hands and feet.” Sudden alarm may produce an illusory enlargement and heaviness of the feet rooting one to the spot. This is particularly the case in dream-states, and also in that interesting condition known as affective hypertonus, or “ night-nurse's paralysis.”

After prolonged immobilisation the parts released may feel unnatural. Orloff de Wet had been manacled by the Gestapo for two years with forearms overlapping and fastened to the waist-belt. Of his eventual release he wrote:

> “ It is a weird sensation to be able to move my hands individually, to be able to hold two things at once, to stretch when I wish . . . and how extraordinary to be able to scratch my back! One's arms detached, how long they feel! Like caged birds, simultaneously happy and perplexed what to do with themselves ” (de Wet 1950).

PSYCHOPATHOLOGICAL ASPECTS OF THE BODY-IMAGE

The body-image, be it realised, lives “ on the fringe of awareness ” and is by no means obtrusive in ordinary circumstances. It is, however, available, and can be brought into consciousness as soon as the stream of attention voluntarily or involuntarily focuses upon it. Probably, then, an obtrusive type of body-image is in itself slightly abnormal, or at least unusual, and connotes an undue measure of introspection. Hence we find the most vivid body-imagery in many intelligent and introverted psychopaths.

The body-image may be altered in very many morbid states, the change taking the form of: (1) enhancement; (2) diminution (or ablation); or (3) distortion.

Pathological Accentuation of the Body-image

Any type of pain, dysæsthesia or discomfort, is liable to cause the affected part to loom largely in the body-scheme, and hence an accentuation (fragmentary or general) is common in many disease states, organic or psychogenic.

Thus, after an operation for acute intestinal obstruction, a patient noticed, whenever he was trying to go to sleep, that his body seemed to consist of a large painful belly, to which were attached very small limbs and a head, and that the whole structure was floating in space “ like a magnetic mine.”

If we turn to neurology for other examples of hyperschematia we can quote almost any case of partial paralysis of a limb, the affected segment usually giving the impression of being too heavy and too big. In cases of Brown-Séquard paralysis the side with pyramidal signs is the one which is hyperschematic, while the other one —with thermanalgesia—appears normal within the body-scheme.

Cases of thrombosis of the posterior inferior cerebellar artery form a particularly interesting study, for the two types of ataxia on opposite sides of the body can be compared. One patient during his convalescence stated that “ the left side [i.e., with thermanalgesia] used to be ‘ all dark ’ which was horrible. I now get mild painful feelings when I stretch, in the muscles, tendons, and joints. This feels painful but lovely because formerly it was a horrible absence. Pain is preferable. Formerly I used to feel a curious awareness in the right [i.e., cerebellar] hand.”

Hyperschematia may be encountered in cases of disseminated sclerosis, as in the following two examples:

> “ The left half of my body is outlined with feeling. I can almost feel the shape of my left shoulder and of my left hip bone . . . The left side seems bigger than the right. Some days my left leg seems bigger than the right, as if pumped up tight. After climbing stairs, my left side seems weighted down, as if I had been carrying a bucket of water. . . . The left ear at times feels as though it did not belong to me.”
>
> “ The left arm and hand often feel of elephantine proportions and as if sharply outlined . . . as if it had an edge to it. (As a child I used to have feelings like this very occasionally in bed at night-time. I am not sure whether I was dreaming or not.)”

A patient with Buerger's disease said: “ the bad leg feels bigger, heavier, and swollen compared with the good one.”

Phenomena of this sort may appear during febrile deliria:

> “ During an attack of gastro-enteritis my little boy had a high temperature and was light-headed. He kept saying that his hands felt much too big.”

degree of adjustment was achieved, so that on the ninth day, when he took off the apparatus, he was once again bewildered and nauseated and he performed wrong movements.

Postural Factors.—These, too, play a great part in determining the nature of the body-image. As Schilder pointed out, the rôle of previous experience is important, and, indeed, habitual postures may be more significant in determining the conformation of the body-image at a particular moment than is the actual posture adopted. For example, in cerebellar disease, when the eyelids are closed, the limbs may take up unusual attitudes without any corresponding alteration in the body-image.

Upsets in the body-scheme are well seen in abrupt lesions in the centres controlling tonus. It was a study of these that led Bonnier (1905) to his conception of "schematia." This author indeed described the vestibular nerve as *le nerf de l'espace.*

The focus of most vivid imagery is probably represented, as Claparède (1924) believed, by a sort of cyclopean eye situated between and somewhat behind the orbits. This may be so even in the blind. Whether this focus is accurately placed at the correct height from the ground is uncertain; or whether there is a general trend towards conventionality. That is to say we do not know whether the body-image of a midget or of a giant is located at the true height or at an imagined "average." Again, when there exists a severe, lifelong crippledom (old rickets, infantile poliomyelitis, or Pott's disease) we cannot say whether the person's body-image conforms to the misshapen reality, or whether it is rationalised so as to fall into line with the normal pattern. A patient of mine, bent and twisted by a gross and old-standing scoliosis, developed, in middle age, a right parietal tumour. The changes in the body-image were, however, no different from those found in other cases of parietal tumour: they did not seem to be influenced in any way by the deformity.

Schilder taught that especially important rôles in the corporeal image are played (1) by the openings of the body, and (2) by the bony prominences. Because of the latter, the effect of gravity is to cause pressure sensations which vary with posture—i.e., according to whether the subject is standing, seated, or lying. Thus the body-image will be correspondingly modified. In collaboration with Parker, Schilder studied the illusory shifts in the "heavy masses of the body" which occur when travelling up and down in a lift. We are reminded in this connection of the sense of imbalance which may be noted when going ashore after a long and stormy sea voyage.

According to Lhermitte (1939) the body-image is very gradually built up during infancy, by the interaction of a number of factors, including (1) painful stimuli; (2) visual impressions; (3) play, which largely entails the repetition of kinæsthetic activities; and (4) libidinous factors. The last-named would no doubt be granted first place by the Freudian psychologists.

It is some years before the body-image becomes stabilised or conforms to what might be called an "adult" pattern. For this reason phantom limbs are rare after amputations in children The plasticity of the body-image in early age is also shown by a study of children's drawings with their anatomical distortions. The same preoccupation with certain bodily parts may be mirrored in the pornographic *graffiti* of the young or immature.

The body-image usually lags behind the physical changes of advancing years. Consequently people rarely realise how old they look to others—despite the periodic evidence of their mirrored reflections.

PROJECTION OF THE BODY-IMAGE INTO OUTER SPACE

A person's idea of his body-scheme rarely remains confined to strict anatomical limits, for it may incorporate certain nearby inanimate objects intimately related with it. A few examples will suffice. One's personality may to some extent include one's clothing, and Head taught that a woman's body-image extends to the very tip of the feather in her hat. A motor-car driver; a cyclist; the pilot of an aircraft—all have for the time being a body-image which includes their vehicle. Thus a motorist who worms his way in and out of city traffic is limited not by his anatomy but by the distance of his bonnet and his off-side mudguard. This type of enhanced body-image does not apply of course to the learner but only to the experienced motorist, cyclist, or pilot. Moreover it does not apply to the passenger within the moving vehicle, for his body-image rarely attains the same measure of unity with the machine as that of the one who guides and directs it.

Inanimate objects other than clothing may be taken into the body-image. Thus a blind man groping his way among unfamiliar surroundings may be regarded as possessing a body-image which extends as far as the ferrule of his stick. A surgeon working with a probe inside a patient's body-cavity, and a soldier confidently manipulating a lethal weapon, are examples of a body-image expanding to include a tool. In such cases, skill is necessary, for a novice awkwardly fumbling with an instrument cannot yet be said to have incorporated the inanimate object within his body-image. An orchestral conductor of unusual psychosomatic sensitivity has said: "When conducting, I feel as if the audience were concentrating upon my baton, of which I become acutely conscious . . . so that it may appear to me extremely heavy."

Then there are occasions when the body-image of one individual becomes unduly aware of the bodies of others. Schilder has stated that the early discovery by a child of certain regions of his own anatomy may lead him to take notice of the corresponding regions in others. The same author also believed that human secretions and excreta remain part of the body-image even after they have been expelled. Partly on this basis he explained the "magical" properties in folklore of fæces, blood, urine, and finger-nails.

Individuals with strong mutual emotional attraction tend to make frequent tactile contact in and out of season: indeed that curious emotional state usually known as "being in love" may even lend itself to the unromantic definition of "a compulsive trend in two body-images of opposite sex towards propinquity, and contiguity, eventually culminating in a total fusion or merger."

RESTLESS PROPENSITIES OF THE BODY-IMAGE

> "We expand and we contract the postural mode of the body; we take parts away and we add parts; we rebuild it; we melt the details in; we create new details; we do this with our body and with the expression of the body itself. We experiment continually with it. When the experimentation with the movement is not sufficient, then we add the influence of the vestibular apparatus and of intoxicants to the picture. When even so the body is not sufficient for the expression of the playful changes and the destructive changes in the body, then we add clothes, masks, jewellery, which again expand, contract, disfigure, or emphasise the body-image and its particular parts" (Schilder 1935).

There is a compelling propensity for most individuals to seek some sort of kinæsthetic satisfaction from frequent and unnecessary bodily movements, all of which bring about a measure of flexibility in the conformation of the body-image. In part at least this may be regarded as a sort of play—i.e., the execution of movements for their own sake. This "ludic" activity can be observed in sport, athletics, and dancing. The antics of the contortionist illustrate the extent to which liberties can be taken with one's body-image, and questions of motivation would give a neurologist abundant food for thought.

sound of the friction produced exaggerated. . . . I seemed to have ears in my finger-tips."

Similar phenomena occur with hashish (Walton 1938), s shown by the following accounts:

"It seemed that my body had dissolved and become transparent" (Gautier 1843).

"The impression was that of wandering out of myself . . . I had two beings" (Urquhart 1850).

"The sensations produced were those of exquisite lightness and airiness . . . I expected to be lifted up and carried away by the first breeze . . . The walls of my frame were burst outward and tumbled into ruin, and without thinking what form I wore . . . I felt that I existed throughout a vast extent of space. The blood pulsed from my head, sped through uncounted leagues before it reached my extremities; the air drawn into my lungs expanded into seas of limpid ether, and the arch of my skull was broader than the vault of heaven. . . . I was a mass of transparent jelly, and a confectioner poured me into a twisted mould" (Taylor 1856).

"Through every thinnest corporeal tissure and minutest vein I could trace the circulation of the blood along each inch of its progress. I knew when every valve opened and when it shut. . . . The beating of my heart was so clearly audible that I wondered to find it unnoticed by those who were sitting by my side. Lo, now, that heart became a great fountain whose jet played upward with loud vibrations, and striking upon the roof of my skull as on a gigantic dome, fell back with a splash and echo into its reservoir . . ." (Ludlow 1857).

"I grew colossal in a delirium of pride. I felt myself the centre of all the world's immortal glory. . . . I was that soul divorced from the corporeal nature, disjoined, clarified, purified. From the air in which I hovered I looked down upon my former receptacle. . . . The chest heaved with the regular rise and fall of breathing . . ." (Ludlow 1857).

"My legs put on a strange, foreign feeling, as though they were waxen pillars underneath me" (Wood 1869–70).

". . . Body growing larger . . . Consciousness of my corporeal existence had somewhat left me though I could see and feel with my hand my lower extremities . . ." (Wiltshire 1878–79).

"He had some feeling of space enlargement and also had ideas of double consciousness. He was himself, yet was somebody else, sitting in a boat, floating through the sky amid pink clouds" (Hamilton 1913).

"The idea of oneness with all nature and with the entire universe seems to take hold" (Schneider 1923).

During the auræ of an epileptic attack, paraschematic sensations may occur. There may be an illusory movement of a limb; the arm may feel as though being torn away from the trunk.

Even in normal persons, the body-scheme may undergo most curious deformations during the predormitum, or period of "sleepening" as Gowers would have said. Federn (1928) has stated that the three-dimensional image may flatten out and become two-dimensional. One diameter may lengthen disproportionately so that the distance between two symmetrical points on the trunk may appear greater than the total length of the body. Median parts of the body-image may disappear, while erogenous regions linger until the onset of sleep.

In those rare but interesting states of ecstasy, there may be extreme aberrations in the body-image sometimes in the nature of a distortion but perhaps more often in the way of what Lhermitte calls "emancipation of the body-image." In states of near-ecstasy, as during strong emotional tension, or better still, absorption in overwhelming auditory stimuli of a musical (particularly an orchestral) character, the body-image may, as it were, be caught up, distorted, or transposed. This was emphasised years ago by Bonnier (1905). Thus a well-known composer said that when conducting, his body-image used to take up a position outside himself, but between his actual body and the players. But after an attack of meningitis this feeling changed, and his body-image would then seem to merge with the music, which would seem to be all around him, behind as well as in front. Or he might get bipartition fantasies with depersonalisation but yet an enhancement of his body-scheme. He might imagine himself a giant bestriding the whole orchestra looking down and watching the players—and himself—all quite small. At other times this feeling was so strong that he would seem to be somewhere within astronomical space, gazing down upon the earth which would look like a small ball.

A professional soprano said that while singing she would become "transported" and seemed to be free of her body and oblivious of her audience. This was particularly the case when singing compositions by Mahler.

Paraschematia may attain fantastic proportions in cases of depersonalisation, whatever the cause, and whether or not accompanied by derealisation. But of greater interest are the phenomena of partial depersonalisation. Lhermitte, who has studied this subject with particular brilliance, speaks of a "bipartition of the postural schema."

Thus the patient of Dr. Noel Harris, already mentioned, developed the illusion of "being two people." He did not actually see or hear his other self, but he would imagine it as occupying a different position in space, the two personalities being situated side by side, but one slightly in front of the other. He would feel that one of his selves was normal and the other not. The abnormal self would urge him to do foolish things.

Bonnier described a patient with attacks of labyrinthine vertigo during which he would seem to be divided into two persons, one looking at the other from outside. Oppenheim's patient had attacks of migrainous vertigo when he felt as though his whole body were doubled or divided (Oppenheim 1916).

One of Lhermitte's patients with vertigo felt the left side of the body "heavy, doughy, as if clamped in steel." The whole left side seemed filled with some foreign matter. Then would come a hemianopia within which would emerge a hallucination of a nearby figure standing to the left and slightly behind, which seemed to be made of a semi-opaque gelatinous substance.

van Bogaert's patient, a diabetic, had attacks of vertigo associated with a hallucination in which she saw a woman enter the door, come near, and then seat herself on her left. This vision resembled the patient, "like a sister."

This delusional dislocation of the body-image into the visual sphere has aroused some psychiatric interest, and which has cropped up a good deal in romantic literature. Spoken of by Féré (quoted by Lhermitte 1939) as a specular hallucination, and by others as "autoscopy," it has been termed by Lhermitte, who has taught us most on this subject, "heautoscopy." Lhermitte has given us examples from Aristotle, Wigan, Goethe, Taine, Alfred de Musset, and d'Annunzio. Others too can be found in de Maupassant and Axel Munthe. He recalls to us the theme of Oscar Wilde's *Dorian Gray* which was based partly on Balzac's *Peau de chagrin* and partly on a tale by Edgar Allan Poe.

Heautoscopy has been encountered in a number of morbid conditions, including drug intoxications, delirium, hysteria, schizophrenia, and demoniacal possession. Certain persons have also claimed the ability at times to emancipate their soul from their body and to bring about by a willed effort a transitory bipartition of the body image, as any theosophist will tell us.

Lhermitte has also discussed the phenomenon of "negative heautoscopy" whereby a patient loses his reflection in a mirror, or even his shadow. Again we are reminded of this as a romantic theme (*Peter Schlemihl*; *L'Horla*). Of a cognate character is the classical *signe du miroir* whereby a patient (often a schizophrene or a dement) fails to recognise himself in a looking-glass, the image appearing like that of a stranger (Klein 1928, Hemphill 1948).

Allied also to autoscopy and bipartition of the body image is the so-called Capgras symptom. Here the

Some of the most vivid and at the same time most bizarre examples of hyperschematia are described by patients with hypochondria. The sensations are often complex, and may be associated with states of partial depersonalisation. One of Schilder's patients said :

> "I have an intense feeling that the right and left sides are interchanged. The right side is too light. Objects feel different in the left hand ; they have more space there. The right hand is much smaller, especially the inner part. When I clench my fist the fingers do not fit my hand . . ."

Dr. Noel Harris has kindly allowed me to quote from a patient who from an early age had periodic episodes in which his hands would seem to increase in size :

> "When I say they grow big I don't just mean that they would be big enough to fill this room, but they are big enough to hold the whole of this hospital, and sometimes big enough to hold the universe."

In the remarkable case reported by Comar (1901), the patient—an ignorant, hysterical girl of 18—was seemingly able to describe the conformation of the viscera while under hypnosis. Describing her associated coxitis, she said "I see how it is with my joint ; it isn't bad, they've made a mistake ; it is simply rusty ; there's fluid inside but not enough to make it work, and there are cords around it which are too tight." Regarding the lower part of her abdomen, she said "How queer it is here in the middle . . . it's a sort of pear with the point downwards, and above on each side are strings which come and turn round in front. There are several covered up in the folds of a veil and in one of the folds there's a thing like a nut." She described her stomach as being "like a big pouch going across with openings above and below. Should I also feel the little folds inside where there are small berries with openings ?" The bladder was said to have "two little tubes going into it and another much shorter one leading out." She described the size, shape and situation of her heart and also the circulation :

> "In the heart I have valves and on one side at the top a big tube leaves, bends over and goes down the middle of the body. . . . These tubes are everywhere ; they go down the arm [pointing to the bifurcation of the brachial artery] . . . they get smaller and smaller. There are two things inside, a white liquid and a lot of little red things, nearly round but not quite. They are flat and they swim about in the white fluid . . ."

It is possible that a difference occurs in the body-image between pregnant women and those with hysterical pseudocyesis. In the former condition, little if any change takes place in the body-image despite the uterine distension, while in the latter condition the swollen abdomen is probably clamant and ever present.

Diminished or Absent Body-image (Hyposchematia ; Aschematia)

Here again the attendant circumstances are diverse. Aschematia is the rule when a segment of the body is deprived of both afferent and efferent communications. Thus it may occur after complete transection of the spinal cord, and the patient may feel as if sawn off at the waist. It may accompany severe painful experiences but only if they are generalised. Electric shocks form an example :

> ". . . Felt myself becoming smaller and smaller and squeezed into myself." (240 V, A.C., contact $^3/_4$ min.)
>
> "My head seemed to enlarge and burst with pain . . . my body, legs, and feet seemed to shrink to nothing until I felt I could stand on a ten cent piece." (22,000 V.)

Hyposchematia accompanies any condition where the action of gravity is actually, or apparently, reduced. Thus in underwater swimming, and more especially in "skin diving," the body and limbs move with ease and freedom, although slowly.

Vertigo constitutes the best examples, and formed the basis for Bonnier's original studies. In these circumstances the patient may seem unduly light ; he may appear to float through the air, or to sink through the bed ; he may seem to be rotated or jerked abruptly in one direction or another.

Lesions of the parietal lobe, more especially of the subordinate hemisphere, afford us some striking instances of ablation of the body-scheme. Even when the dominant hemisphere is involved we may discern traces of disordered body-image in an autotopagnosia, best shown in the finger agnosia of Gerstmann's syndrome. When the right parietal lobe is involved in dextrad subjects, we may encounter defects ranging from neglect of the left half of the body to hemidepersonalisation and anosognosia (or unawareness of hemiplegia). On top of these negative aspects, certain delusional and confabulatory systems may be added. Thus a patient who had sustained an embolism of his right middle cerebral artery, reported that ". . . it felt as if I was missing one side of my body (the left), but it also felt as if the dummy side was lined with a piece of iron so heavy that I could not move it . . . I even fancied my head to be narrow, but the left side from the centre felt heavy, as if filled with bricks." At one time he thought that his paralysed leg belonged to the man in the next bed. His body felt to him half as wide as it should have done. Lying on the left side gave him the sensation that he was "lying on a void" . . . that he was at the extreme edge of the bed and would presently fall off. In the early days he also felt that he had no penis at all. On this account he was clumsy with the urinal and the bed was frequently soiled. His sensation of owning a penis returned quite suddenly one morning in association with an erection, and it afterwards felt normal.

We may refer in passing to two interesting sensory defects due to a dissociation between a loss in the body-image and an integrity of sensation. When the body-image is in abeyance over one half only, sensory stimuli may be felt but incorrectly localised to a corresponding point on the other side (alloæsthesia). When the body-image is universally lost, painful contacts may be felt but completely unlocalised (achiria ; pain asymboly).

Distortion of the Body-image (Paraschematia)

This may accompany hyper- and hypo-schematia, so as to give a mixed picture. Or it may consist in spatial alterations of the body-image. Some of the best examples are to be found in states of intoxication with drugs.

Quoting from the monograph on mescal hallucinations by Kluver (1938), we may refer to the person who said he could see and feel his thorax constantly growing until it became a garden in which the arms were alleys. In another case the right half of the body was felt to be continuous with the surroundings. Another stated "my arm becomes suddenly long." A leg may seem several metres in length. Or, sometimes the whole body seems smaller. Limbs may feel "swollen" or they may "melt away."

Still more complicated phenomena may take place. Thus Serko (1913) said :

> "I felt my body particularly plastic and minutely carved. At once I had a sensation as if my foot was being taken off . . . then I felt as if my head had been turned by 180 degrees. My abdomen became a fluid, soft mass, my face acquired dimensions, my lips swelled, my arms became wooden, my feet turned spirals and scrolls, my jaw was like a hook and my chest seemed to melt away."

Again, in Knauer and Maloney's (1913) account :

> "I realised that I had no head, but in its place a sheet of ground glass, such as is used in a camera as a screen . . . where my ear was, was an insoluble mystery ; I could not find it so long as with open eyes I followed and controlled the movements of my searching hand. I was quite unconscious of the position of any part of my body."

One of my subjects, a painter, developed under mescal a curious cutaneo-auditory hyperæsthesia :

> "When peeling a banana I heard every shred straining and cracking ; when stroking anything I heard the small

TUBERCULOUS MENINGITIS IN CHILDREN

RHYTHM OF TREATMENT, PROGNOSIS, AND RESULTS

DERMOD MACCARTHY
M.D. Lond., M.R.C.P.
ASSISTANT TO THE PROFESSOR OF CHILD HEALTH, UNIVERSITY OF LONDON

TREVOR P. MANN
M.D. Lond., M.R.C.P.
LATE REGISTRAR TO MEDICAL RESEARCH COUNCIL'S STREPTOMYCIN UNIT; ASSISTANT TO THE PROFESSOR OF CHILD HEALTH, UNIVERSITY OF LONDON

From the British Postgraduate Medical School of London, and Institute of Child Health, University of London

THREE years have now elapsed since the start of the Medical Research Council trials of streptomycin in tuberculous meningitis; and, though much experience has been gained and opinion is beginning to harden in favour of certain lines of treatment, the last word about dosage and rhythm has not yet been said. Sulphones and other drugs are now commonly used in addition; but streptomycin still remains the most important therapeutic agent, and it is desirable to decide, if possible, what is the best that streptomycin alone can achieve.

We have therefore reviewed the treatment of 43 children (all under the age of 7 years except 2 aged 8 years) who were admitted under the M.R.C. scheme and treated with streptomycin on four different plans; 16 of these cases were included in the preliminary report of the Medical Research Council (1948) trials of streptomycin in tuberculous meningitis. The first child was admitted on Jan. 20, 1947, and the last on June 21, 1948. All the survivors have been followed up to Oct. 1, 1949. The minimum observation period for survivors is sixteen months, and the survival-rate for this period is 41%. Two children have been observed for two years and eight months.

The recovery of a child from tuberculous meningitis may depend on several things besides streptomycin or the manner of its administration—e.g., age, advancement of tuberculous lesions other than meningitis, clinical state at start of treatment, innate resistance to tuberculosis, and the quality of nursing and medical supervision. The number of cases affording a true comparison that can be collected by one team is therefore small. Added to this there is the difficulty often encountered in adhering strictly to a prescribed plan of treatment. The statistical approach to the problem of deciding which of many different rhythms of treatment gives the best results has not yet yielded an answer, and we have still to depend on the conclusions of treatment centres which have dealt with fair numbers. Our own series is relatively small and not suitable for statistical analysis, but some useful conclusions can be drawn from these cases, and our results are presented in a form which we hope will enable other centres to compare them with theirs (figs. 1 and 2, tables I and II).

DEFINITIONS

Normal Cerebrospinal Fluid.—The standard of normality that we have adopted is: cells 5 or less per c.mm.; protein 40 mg. or less per 100 ml.; and glucose 45 mg. or more per 100 ml.

Nearly Normal Cerebrospinal Fluid (final stage of recovery of C.S.F. in cases off treatment or on extended intramuscular treatment).—In the earlier part of the trials the attainment of a normal C.S.F. by any patient clinically recovered was considered tantamount to apparent cure, but we very soon found, when more frequent follow-up lumbar punctures were done, that a normal cell-count, protein level, and glucose level in the C.S.F. on one occasion was almost always followed in succeeding weeks by slight deviations of the protein and cells from their normal values. Only after many months do the various elements of the C.S.F. remain constantly within normal limits. Generally the first element to return to normal is the glucose, next the cells, and last the protein (fig. 3). The glucose may be within normal limits for six months or more while the cells and protein are still fluctuating between normal and slightly abnormal levels. We have come to be suspicious of a cell-count fluctuating for a long time between 10 and 20 per c.mm. as probably foretelling relapse. The higher the protein at the beginning the longer it takes to come down.

Initial Response.—By this we mean the first signs of a return towards normal—not merely an arrest of deterioration but a step in the reverse direction. We have not regarded as a response the mere prolongation of life beyond the expected time, or the continuation of a certain clinical state without change for better or worse. The essential sign of a return towards normal is an improvement in the mental state. We have found the definitions of mental states given below useful in following the patient's progress in deterioration or towards recovery. Only in cases where the mental state was normal from the start have we considered the absence of deterioration, so to speak, as a response. The state of nutrition has little correlation with the initial response, except when the meningitis is mainly confined to the spinal cord and posterior cranial fossa. In such cases the mental state remains for a time unclouded, but deterioration may be shown by very rapid emaciation. If nutrition is well maintained in the early weeks this is all to the good, but some wasting is compatible with a satisfactory initial response; it is in assessing subsequent progress that the weight-curve is most useful. We have therefore taken the mental state as the only guide in timing the initial response. The important bearing of this on the final results is discussed later.

Full Recovery.—This term applies to the child who has no symptoms or signs of meningitis, who is in good health and leading a normal life without restrictions, and whose C.S.F. *has been normal on two occasions* in a minimal period of three months. Neurological sequelæ, if static or improving, do not invalidate the definition.

Relapse.—We reserve this term for patients who have made a "full recovery" or who are perfectly well with a "nearly normal C.S.F." and then develop fresh symptoms and signs of tuberculous meningitis.

patient has the mental impression, but not an actual hallucination, that he is not alone. This is an event which may develop in states of exhaustion, hunger, or thirst, in which loneliness is conspicuous. Hence it has been described by Antarctic explorers, by solitary travellers, shipwrecked sailors, and by climbers marooned upon the Alps.

PHANTOM SENSATIONS

The occurrence of phantom-limb sensations after an amputation constitutes the best-known evidence of a body-image. There is no necessity to recapitulate the extensive literature of the subject, but one or two aspects are worthy of emphasis.

In the first place phantom limbs are to be expected in the vast majority of all amputees, unless the limb is lost in very early life. In those born without one or more limbs, whether or not due to intra-uterine amputation, phantom sensations do not occur.

The ordinary phantom limb may participate in any widespread process of dysæsthesia. Thus a supervening diphtheritic polyneuritis will produce numbness, tingling, and pins-and-needles sensations in the phantom limb as well as the others. Even sensations of heat, or of coldness, environmentally determined, will be referred to the missing limb.

According to Leriche (1937), phantom sensations apply only to limbs. Riddoch (1941), however, mentioned that one may encounter a phantom nose or penis, and he believed that loss of any extruding part of the anatomy was liable to be followed by a phantom. Dr. L. G. Kiloh, my registrar at King's College Hospital, has kindly investigated this question for me on a series of surgical patients. According to his findings, phantom feelings are rare after removal of a breast or ear, but common after enucleation of an eye, excision of the rectum, or laryngectomy.

The following are some of the statements made by these surgical patients.

Loss of an Eye

CASE 1.—" Yes ! My right eye feels very active. It is strange that you should ask. I could almost feel that it is still there. It is hard to realise it has gone—I still feel as though I am using it."

CASE 2.—" Oh yes, definitely ! You think that you can still feel through it."

CASE 3.—" Yes, I get exactly the same thing as a phantom limb. I feel as if I had nothing missing whatsoever. It feels as if I have got my hand in front of my eye—like a pad ; and if I could take the pad away, I would see."

Abdominoperineal Excision of Rectum

CASE 1.—" I often get the feeling that I am making a motion—especially when I make water. I have to look in the pan to make sure that I haven't."

CASE 2.—" Sometimes when I wake up I feel as though I want to go to the lavatory, but of course I do not bother to sit down now. If I think about it, it does still seem to be there."

CASE 3.—" I may still feel that I have an anus and that something wants to come through. This feeling occurs once or twice a week."

Phantom feelings may occur not only after amputation but also after lesions of the nervous system, especially peripherally. Thus a phantom arm may follow an injury to the brachial plexus. A phantom anus may occur after a lesion of the conus medullaris. Transverse spinal disease may cause a paraplegia with phantom legs. Even a cerebral lesion may, very occasionally, give rise to a phantom third arm and leg in addition to the hemiplegia.

MUTILATING OPERATIONS

It is perhaps not unfair to say that many surgeons are ignorant of the extent to which some of their operative measures produce a prolonged and crippling afront to the ego—particularly in the case of young women. Certainly some dental surgeons do not hesitate to sacrifice the front teeth of a young woman upon the altar of focal sepsis, and thereby go far towards ruining the patient's self-esteem. Plastic surgeons, far more than thoracic or abdominal surgeons, are conversant with the severe psychological trauma which their patients suffer, out of all proportion to the local lesion. In the same way skin diseases, especially of the exposed parts, bring in their train much more mental suffering than the mere discomfort justifies.

We might continue the discussion by comparing the social and sexual sequelæ which are apt to follow the loss of a leg as opposed to an arm ; or to consider the assault upon the personality of the enucleation of an eye, or the amputation of a breast.

It is feared that these non-surgical considerations are not always given enough weight when the pros and cons of operative interference are discussed.

NATURE OF THE BODY-IMAGE IN MONSTERS

Already we have debated whether the body-image conforms to the actual morphology of the body, or whether it adheres to a more general group-pattern. It is interesting to speculate what kind of body-scheme would belong to one of those rare and grotesque freaks of nature should it ever survive to adulthood and to some sort of social existence. The most striking subject for conjecture would be a bicephalic or two-headed monster. Although most of these perish early, some have attained adult stature—e.g., the Tocci brothers and the Sassari twins.

Personal identity must not be confused with body-image, though the two conceptions overlap to some extent. It would be safe to assume separate " personalities " and discrete body-images to such conjoined pairs as for instance the Siamese twins. But when we consider a single monster with one trunk, one set of viscera. and two heads and necks, there is abundant room for differences of opinion. When the Sassari twins were born in 1829, a contemporary journal wrote " Already it is a matter of grave consideration with the spiritualists, whether they had two souls or one ; most of them think the twins had two as sometimes one of the heads cried and the other did not." (Quoted by Thompson 1930.)

There are other grounds for thinking that a bicephalic creature would possess two separate egos. This belief is supported by the behaviour of the two-headed tortoise filmed and studied in detail by Brickner and Lyons (Brickner 1948). The two heads were often in actual combat with each other.

A bicephalic human monster would probably also be endowed with two identities, but the body-image would be, to say the least of it, complicated. The ridiculous situation might be imagined where such a monster, having two egos and but a single body, might have very differing likes and dislikes. Do both components sleep at the same time ? Do both suffer hunger and thirst simultaneously ? Probably not, or not necessarily so. One can visualise the one partner having a liking for an article of diet which might prove indigestible to the common alimentary tract. One partner might choose to exercise and the other to rest. One might favour the eatables, the drinkables, the clothing, even the acquaintances which the other partner abhors. A little imagination will call up a wide variety of other possible predicaments. . . .

of meningitis on admission to hospital; for the accuracy of this history largely depends on the mother's memory and acuteness of observation and on the clinician's experience in bringing out the facts. Furthermore, there is little correlation between length of history and immediate response to treatment—cases with a long history may do very well, and vice versa. We have therefore sought a simpler and more accurate method of assessment.

The state of advancement of the meningitis is probably closely paralleled by the height of the intracranial pressure, and the resulting cerebral depression is more closely reflected in the child's mental state than in any other symptoms or signs. We have therefore assessed the mental state of all our cases on admission according to the following criteria:

Stage 1.—Normal mentality of a sick child, more or less modified by drowsiness, irritability, and headache.

Stage 2.—Delirious: confused mental activity.

Stage 3.—Stupor: (*a*) Accessible—i.e., obeys simple commands; may recognise parents; exhibits little or no spontaneous activity. (*b*) Inaccessible by speech or sight; rousable only by painful stimuli or shaking; does not recognise parents.

Stage 4.—Coma: a state of absolute unconsciousness as judged by the absence of any psychologically understandable response (including, for example, change of expression) to external stimuli or inner needs; the patient may reach still lower levels of nervous disintegration—e.g., loss of swallowing reflex (see Glossary of Psychological Terms, *Med. Res. Coun. War Memo.* no. 4. London. 1941).

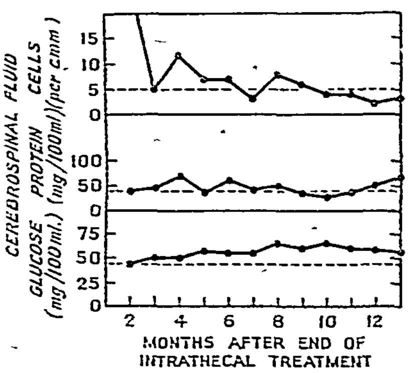

Fig. 3—Example of final stages of recovery of C.S.F. in cases off treatment or on extended intramuscular treatment (case 35).

Except for 3 infants under the age of a year we have had no difficulty in placing a patient in one or other of these categories. By adopting this method we have minimised personal bias and subjective impressions and made the assessment of mental state (and, by inference, the advancement of the meningitis) almost as objective as a physical sign. The following data and fig. 4 show clearly the serious prognosis that goes with stupor or coma:

Mental state	*Recovered*	*Died*	*Total*
Stage 1	10	8	18
,, 2	2	3	5
,, 3 (stupor or coma)	2	15	17
Infants, not assessable (cases 16, 20, and 37)	1	2	3
Total			43

Cases on intramuscular treatment (plan c) not included.

EFFECT OF PULMONARY INVOLVEMENT ON PROGNOSIS

The survival-rate according to the presence or absence of a primary complex demonstrable by X rays was as follows (see also fig. 5):

	Total	*Dead*	*Alive*
Primary complex	19	16	3 (*16%*)
No primary complex	24	13	11 (*46%*)

In many of the fatal cases we had to be content with the evidence of a single portable X-ray film. In 10 such cases radiography was negative. In 5 of these a necropsy was done, and a primary complex was found in 3 of them. The number of fatal cases associated with a primary complex was therefore probably greater than the radiological evidence showed. In the survivors, on the other hand, it seems unlikely that a primary complex would be missed, for here we had ample opportunity of taking repeated films of good quality in the X-ray department.

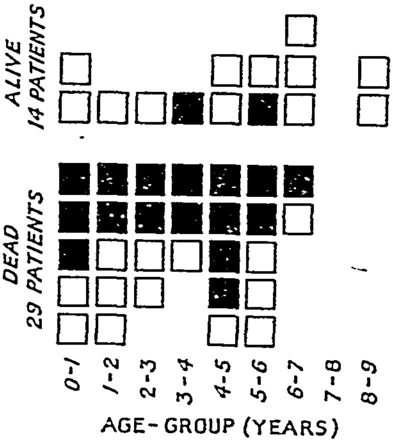

Fig. 4—Prognosis according to age and mental state on admission: blank squares, stages 1 and 2; black squares, stage 3.

The evidence tabulated above suggests that tuberculous meningitis has a worse prognosis when associated with an active focus of primary tuberculosis, and the difference is statistically significant; but, since the numbers are small, perhaps the importance of this observation should not be overemphasised.

RESULTS ACCORDING TO INITIAL RESPONSE

If we consider the over-all results in terms of the initial response made by these children, the responses may be divided into three types.

(1) *Immediate response*—i.e., in the first week—was seen in 13 patients, all on combined treatment, and 3 of them may be described as exceptionally responsive. All of them made steady progress on their first course of treatment. Only 3 have died, 2 after recrudescence and 1 after relapse; 3 have not yet fully recovered after sixteen months.

(2) *Delayed response.*—Of the 10 patients (3 on intramuscular treatment alone) showing this type of response, 5 have died, 3 after a recrudescence and 1 after a relapse. The delay varied from two to eleven weeks. In most of these children progress was slow, and neurological complications were more numerous in this group than in the first, comprising blindness and optic atrophy (2 cases), uncinate fits, hemianopia, and lethargic encephalitis picture (1 case), 7th nerve palsy and paraplegia in flexion (1 case), thalamic state (1 case), and hemiplegia (1 case). Cases with neurological complications are emphasised by Bernard et al. (1949) as having a greater tendency to relapse.

(3) *No response.*—Of the 20 patients (4 on intramuscular treatment alone) who did not respond, 15 were admitted in mental state 3. In a few cases treatment was abandoned for various reasons, for we were always dominated by fear of the late results of such disasters as cerebral softening or extreme wasting of cerebral tissue associated with gross hydrocephalus, conditions which are often demonstrable post mortem. Two of our recovered patients are mentally retarded; case 37 is only slightly backward, but case 10 is an idiot. A quicker resort to ventricular drainage or surgical intervention in the acute stage might have allowed more streptomycin to reach the C.S.F. and might perhaps have prevented hydrocephalic attacks in some of these patients; but we are not convinced that any treatment so far devised can make much impression on this type of case.

Recrudescence.—This term refers to children with an abnormal C.S.F. but otherwise well, who deteriorate soon after treatment is stopped.

SELECTION

In our series there has been no deliberate selection of cases, but it has been difficult to eliminate this factor completely. For instance, when the Emergency Bed Service was responsible for placing cases in the few streptomycin centres then existing, it was not unusual for several children to be waiting for treatment. In these circumstances it was natural to choose what appeared to be the most favourable case from those presented to us over the telephone. There has been no selection of cases after admission to hospital. All cases in which the diagnosis was confirmed are included in this review.

BASIS OF DIAGNOSIS

In 40 cases bacteriological proof of the diagnosis was obtained by positive film (47%), culture (63%), or guineapig inoculation (88%), but 3 cases are included in the series although film, culture, and guineapig inoculation were all negative, for the following reasons.

Case 9.—Diagnosis confirmed post mortem.

Case 10.—Girl, aged 9 months. Pulmonary tuberculosis (tubercle bacilli in stomach washings). Mantoux 1/1000 positive. Sixteen days' history of vomiting and convulsions; C.S.F. found at another hospital to contain: cells 30 per c.mm. (lymphocytes) and protein 35 mg. per 100 ml (glucose not tested); film negative, culture not set up. On admission six days later C.S.F. contained: cells 100, protein 45 mg. and glucose 19 mg. per 100 ml. Baby was unable to sit up, whereas previously it had been bright and cheerful and was starting to sit alone. Became stuporose during third and fourth weeks of treatment, and glucose in C.S.F. fell to 0. Glucose remained low for eight weeks and did not regain a normal level till the fifteenth week. Baby emerged from stupor in the sixth week but remained permanently mentally retarded and with right arm and leg spastic. Convulsions recurred in twentieth week but not subsequently. Developmental tests at the age of 3 years and 2 months gave her a developmental age of about 1 year. This case is included in the series because it is hardly possible to explain the association of pulmonary tuberculosis, vomiting, and convulsions with the C.S.F. changes by any other diagnosis than tuberculous meningitis, and to exclude her would be to lose sight of one of the risks which recovery from tuberculous meningitis involves in small children.

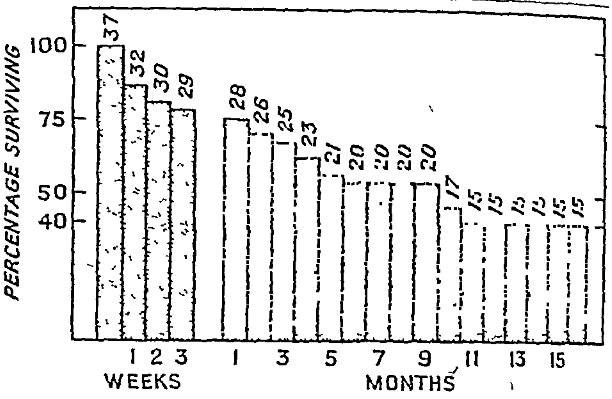

Fig. 1—Survival-rate in 37 cases on combined treatment according to time elapsed from start of treatment (shortest observation period 16 months).

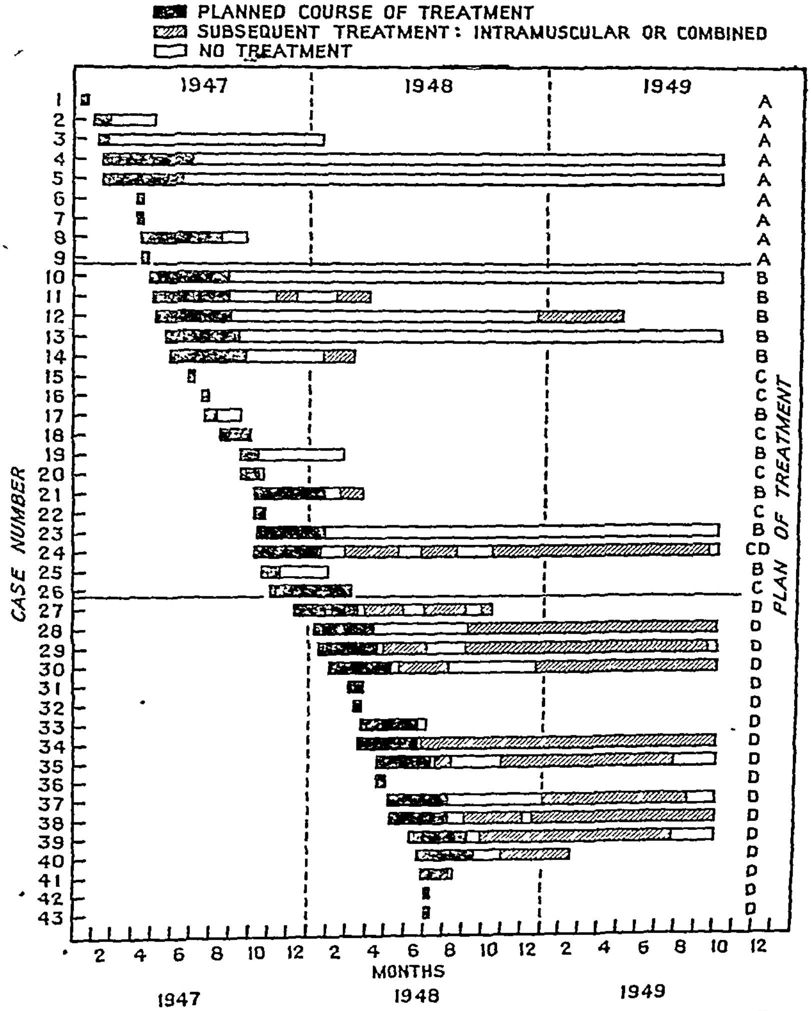

Fig. 2—Length of survival, duration of treatment, and plan of treatment adopted. For plans A, B, and D see fig. 6. Plan C, intramuscular streptomycin alone. Treatment abandoned in cases 2, 3, 17, 19 and 25.

Case 37.—Boy, aged 7 months. Close contact with tuberculous adult. Mantoux 1/1000 positive. X-ray film of chest showed primary complex. Extreme irritability. C.S.F. contained: cells 158 per c.mm. (lymphocytes 90%), protein 500 mg. and glucose 5 mg. per 100 ml. Glucose remained low for three weeks on treatment. Excellent response, but developmental tests after recovery showed slight retardation.

MENTAL STATE AND PROGNOSIS

The extent and severity of the meningitis at the start of treatment have a considerable bearing on the prognosis. The results are in general much better in "early" cases than in "advanced" cases treated in the same way. The extent to which a series is adversely weighted by advanced cases is therefore important in comparing the results of two schemes of treatment or the results in two centres. The commonly used subdivisions—"early," "medium," and "advanced"—are vague, however, and the observer assessing the state of advancement of the meningitis may be influenced by such things as the degree of meningism, the presence of neurological signs, and perhaps the length of the history.

Rubie and Mohun (1949) emphasise apathy and various degrees of withdrawal from the environment as indicating a raised intracranial pressure and they give prominence to the mental picture, though chiefly as an aid to the diagnosis of tuberculous meningitis. They rightly discount the length of history as a guide to the stage their early detection should depend more on a careful planned clinical examination than on too frequent lumbar punctures. We therefore recommend a special watch on the following points:

(1) *Temperature chart:* Rectal readings should be taken morning and evening. Fever for several days, unexplained by intercurrent infection or tuberculous activity outside the nervous system, should suggest the possibility of recrudescence or relapse, and the other confirmatory signs set out below should be sought for.

(2) *Weight chart:* The child should be accurately weighed twice a week and the readings plotted graphically. A steadily falling weight should be considered an ominous sign, especially when associated with a return of fever.

(3) *Headache, vomiting, and enuresis:* The nurses must record these tell-tale symptoms on the temperature chart. The presence of any one of them for more than twenty-four hours demands immediate examination of the C.S.F.

(4) *Mental and personality changes:* Nurses or visiting parents are often the first to note these changes and should be asked to report them promptly.

Evolution of Plans of Treatment

In the original M.R.C. trials dosage at the rate of 0·02 g. of streptomycin per lb. of body-weight per day intramuscularly and 0·1 or 0·05 g. intrathecally was more or less closely adhered to, but there was much experimenting with rhythm of treatment. The treatment is an ordeal; and it was therefore urgently necessary to find out whether less arduous treatment would give over-all results comparable to those achieved with long courses. Intramuscular streptomycin alone has produced clinical recovery and a normal C.S.F.—Rubie and Mohun (1949) reported 2 cases, and Daniels (1949) a further 2 cases—but the over-all results of this treatment have been too bad to justify its further use. Information obtained in the M.R.C. trials (Medical Research Council 1948) suggested that, when intrathecal injections were given for relatively brief periods and there were frequent interruptions with relatively long intervals of no treatment, the results were better than those of prolonged continuous combined therapy. At the same time, a general clinical improvement often followed the temporary cessation of injections. These observations led us to change from continuous treatment to a course of treatment with rest periods (plan B), and later to a considerably shorter course (plan D), also with rest periods.

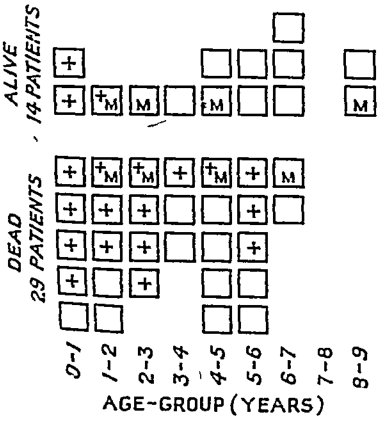

Fig. 5—Prognosis according to age and presence or absence of primary complex (+) and miliary tuberculosis (M).

Fig. 6 shows the three plans of combined treatment (A, B, and D) used. The dosage recommended by the M.R.C. was adhered to in all cases except the few in which toxic effects or local reactions obliged us to reduce it.

Before any patients were treated on plan D it was decided that those who had not responded adequately to a single course, as determined by the clinical state or the C.S.F., should receive the whole course, or part of it, again. Later, when relapses had been encountered, we began to give continuous prophylactic intramuscular cover to all. More recently we decided to give alternate periods of three weeks' intramuscular treatment and two weeks' rest, during which the child could go home. (These "holidays" have been welcomed by the children and their parents, not to mention the nurses, and the results so far in 6 such cases have been entirely beneficial.) Thus no limit was set to the amount of treatment that might be given on this plan; in effect, it could now be summed up as a course of combined treatment as in fig. 6 (D) with repetition of the whole or parts of the course according to progress, and prolonged continuous or intermittent intramuscular cover until the C.S.F. has been normal on two occasions in three months.

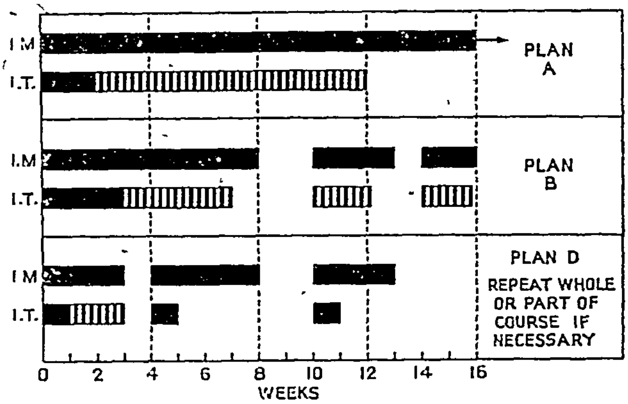

Fig. 6—Plans of combined treatment used; intrathecal injections given either daily (black) or on alternate days (barred); plan C (intramuscular treatment alone) not shown.

COMPARISON OF RHYTHMS OF TREATMENT

The response to different rhythms of treatment should not be confused with the patient's initial response. In our experience a good initial response depends mainly on early diagnosis and a free circulation in the cerebrospinal spaces. The younger the patient the more advanced is the disease likely to be and the more troublesome the mechanical obstructions to the flow of cerebrospinal fluid; but, provided that streptomycin can reach the affected tissues, a clinical response can nearly always be obtained by combined therapy in the early weeks of treatment. It is from this stage onwards that the advantage of one rhythm of treatment over another may appear.

The results of the different plans of treatment are analysed in table I. This analysis includes all cases whether they responded to treatment or not. But in trying to compare the efficacy of the different rhythms of treatment we have dealt only with cases that made an initial response (see definition) and in which the course was completed; for it is only in these that a rhythm of treatment can show its effect.

Two other cases which were eliminated from the analysis should be mentioned separately:

Case 32.—This boy died on the eleventh day from a subdural hæmorrhage due to thrombocytopenic purpura. He had miliary tuberculosis, and the thrombocytopenia was considered to be a complication of this rather than a toxic effect of streptomycin. He had not responded to treatment up to the time of his death.

Case 24.—Here intramuscular treatment alone (plan C) was given for eighteen days, and thereafter combined treatment was started because of low C.S.F.-streptomycin levels. Combined treatment was stopped after a month, but intramuscular injections were continued with rest periods. After a recrudescence, repeated courses (plan D) were given for fourteen months; finally, continuous intramuscular treatment was given for five months. After two years this child is alive and well, without sequelæ, and treatment has been stopped. His C.S.F. shows: cells 5 per c.mm., protein 55 mg., and glucose 57 mg. per 100 ml. Since the treatment has not conformed very closely to any of the given plans, particularly in the first three months, he cannot be included in any group; but we think of him as belonging to plan D.

Recrudescence and Relapse

After the last intrathecal injection of a course the C.S.F. is always abnormal, whatever the clinical state of the patient. This abnormality may be due to the persistence of the meningitis or to the residual irritative effects of the streptomycin on the pia arachnoid, or to a combination of both, and it is impossible to foretell the future trend of the C.S.F. elements. In other words, the question of activity or quiescence of the meningitis and the need for further treatment, must depend on close observation in the next few weeks. Unfortunately one cannot be guided by the patient's clinical state for, whatever the ultimate outcome, there is usually an all-round clinical improvement for several weeks after the intrathecal treatment has been stopped. During this period the intramuscular streptomycin continues to exert a suppressive action; but, when the intramuscular treatment is stopped, a recrudescence follows sooner or later in cases where the meningitis has remained active.

We think it worth while to distinguish between "recrudescence" and "relapse," and we have already defined these terms. In the relapse group we must suppose that the greater part of the meninges has been cleared of infection, and the flare-up is due to reinfection from a small stronghold of active meningitis, usually in the interpeduncular region. Recrudescence, on the other hand, is probably due to persistence of a more diffuse meningitis, temporarily suppressed by streptomycin but released when treatment is withdrawn.

Recrudescence

Recrudescence occurred in 8 of our cases; in 2 of them it occurred twice, making 10 examples in all. It is significant that, with 2 exceptions, they all followed our latest scheme of treatment (plan D). Five of the recrudescences began within a month of discontinuing the intramuscular part of the course. One started in a rest period and not at the end of the course of treatment, but this is the only recrudescence we have seen in a set rest period. The 4 remaining examples happened six, seven, eight, and eleven weeks after the course of treatment. Of the 8 children who had a recrudescence, 4 are now alive and well, including the 2 children who had two such episodes. The remaining 4 have died; in 1 of these (case 27) the tubercle bacillus had become resistant to streptomycin.

Case 38.—Plan D. Now alive and well. First recrudescence a month after last intramuscular, and six weeks after last intrathecal, injection. Activity of meningitis suggested first by weight loss and fever, and then more definitely by headache, vomiting, irritability, and return of papillœdema. No meningism. C.S.F. cell-count rose from 17 to 75 per c.mm., and the protein from 100 to 160 mg. per 100 ml., while the glucose fell from 53 to 38 ml., confirming the clinical impression of recrudescence. A second recrudescence occurred three weeks after the second course of combined treatment. The symptoms and signs were identical with those that heralded the first, except that there was no pyrexia. Papillœdema reappeared for the second time. The C.S.F. cells and protein reflected the clinical deterioration, but the sugar level, already low, fell only slightly.

The most prominent early symptoms and signs in this group were headache, vomiting, drowsiness, fever, and loss of weight. In 2 children loss of bladder control first suggested reactivation of the meningitis. In another child, who had two recrudescences, both were heralded by the reappearance of gross papillœdema. Meningism was a most inconstant sign and was therefore of little value in the early diagnosis of recrudescence. In only 1 case did the C.S.F. findings of routine lumbar puncture suggest the diagnosis before clinical signs appeared, though most of this group had had for some time a persistently abnormal C.S.F., often with a low glucose level, a state of affairs we now regard as a probable precursor of recrudescence, and an indicatio for resuming treatment.

Relapse

There were 4 relapses in our series, including 2 i patients who had attained a normal C.S.F. Case 1 remained in good health for fifteen months after th end of treatment, but all this time the C.S.F. finding were never quite within the normal limits. His sudde and rapid deterioration when he relapsed was unchecke by a second course of treatment. The other 3 relapse arose much sooner after the end of treatment—three four, and four and a half months. Of the 4 children cases 28 and 30 recovered with further treatmen and are now well. It seems likely that the relapse i case 28 was precipitated by a pneumo-encephalogram which had been done ten days previously.

Case 12.—Plan B (plan D for relapse). Died. No abnorma signs at the end of treatment. After a long convalescence at the seaside, where he successfully weathered an attack of whooping-cough and (later) measles, this boy was allowed home and back to school. Numerous lumbar punctures during the year before his relapse showed a slightly abnormal C.S.F (cells 10–20 per c.mm., protein 25–55 mg., and glucose 40–6 mg. per 100 ml.). The relapse symptoms, which began fifteen months after the last injection of streptomycin, consisted of headache, vomiting, photophobia, insomnia, and character change. There was no fever and no loss of weight, but there had been no gain for the previous two months, during which period the boy had been off his food and had occasionally vomited. On readmission he had no abnormal signs and no meningism. (C.S.F. cells 100 per c.mm., protein 80 mg., and glucose 54 mg. per 100 ml.) Organism sensitive. Slow deterioration on treatment (plan D).

Case 28.—Plan D. Now alive. Normal C.S.F. three and a half months after the end of treatment. A residual left 6th nerve paresis and minimal papillœdema were still present, but the latter was discounted in the face of a normal C.S.F. An encephalogram was done ten days before the reappearance of symptoms. The first relapse symptoms appeared four and a half months after the end of the course and consisted of loss of bladder control, shortly followed by headache, vomiting, and drowsiness. On readmission the boy was afebrile, but meningeal signs were present and he was drowsy and irritable. His C.S.F. showed cells 19 per c.mm., protein 55 mg., and glucose 54 mg. per 100 ml., suggesting early relapse. He has responded to further streptomycin.

In these 4 relapses, headache, vomiting, and loss of weight, with the addition of personality changes, were again the most constant presenting features. But, in contrast to the recrudescence series, fever was absent in 3 of the 4 cases. The fourth case had occasional spikes of temperature for several weeks before the relapse but these were attributed to the activity of another tuberculous focus. Meningism was completely absent in 2 of the 4 children at the time of the relapse. The diagnosis was first suggested in all 4 cases by clinical findings, subsequently confirmed by C.S.F. changes. The C.S.F.-*glucose level remained normal* in 3 of the children, which contrasts oddly with its value in the initial diagnosis of tuberculous meningitis.

Early Diagnosis of Recrudescence and Relapse

The gloomy prognoses we gave at the time these setbacks were encountered have not been fulfilled. Altogether, 7 of the 11 children are alive and well, 2 of them after a repeated episode. Among the survivors only case 28, who had a relapse, still causes concern. With early detection and prompt treatment it seems that, at least in the recrudescence group, the ultimate outlook is not necessarily bad.

Once we were alive to the danger of recrudescence and relapse we began to examine the C.S.F. every week in the post-treatment period until it showed a favourable trend. Thereafter lumbar punctures were done at slightly increasing intervals. In spite of this precaution, all the relapses and all but one of the recrudescences were first suspected on clinical grounds, and we now believe that their early detection should depend more on a careful planned clinical examination than on too frequent lumbar punctures. We therefore recommend a special watch on the following points:

(1) *Temperature chart:* Rectal readings should be taken morning and evening. Fever for several days, unexplained by intercurrent infection or tuberculous activity outside the nervous system, should suggest the possibility of recrudescence or relapse, and the other confirmatory signs set out below should be sought for.

(2) *Weight chart:* The child should be accurately weighed twice a week and the readings plotted graphically. A steadily falling weight should be considered an ominous sign, especially when associated with a return of fever.

(3) *Headache, vomiting, and enuresis:* The nurses must record these tell-tale symptoms on the temperature chart. The presence of any one of them for more than twenty-four hours demands immediate examination of the C.S.F.

(4) *Mental and personality changes:* Nurses or visiting parents are often the first to note these changes and should be asked to report them promptly.

Evolution of Plans of Treatment

In the original M.R.C. trials dosage at the rate of 0·02 g. of streptomycin per lb. of body-weight per day intramuscularly and 0·1 or 0·05 g. intrathecally was more or less closely adhered to, but there was much experimenting with rhythm of treatment. The treatment is an ordeal; and it was therefore urgently necessary to find out whether less arduous treatment would give over-all results comparable to those achieved with long courses. Intramuscular streptomycin alone has produced clinical recovery and a normal C.S.F.—Rubie and Mohun (1949) reported 2 cases, and Daniels (1949) a further 2 cases—but the over-all results of this treatment have been too bad to justify its further use. Information obtained in the M.R.C. trials (Medical Research Council 1948) suggested that, when intrathecal injections were given for relatively brief periods and there were frequent interruptions with relatively long intervals of no treatment, the results were better than those of prolonged continuous combined therapy. At the same time, a general clinical improvement often followed the temporary cessation of injections. These observations led us to change from continuous treatment to a course of treatment with rest periods (plan B), and later to a considerably shorter course (plan D), also with rest periods.

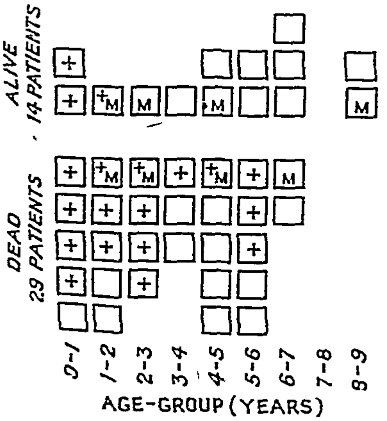

Fig. 5—Prognosis according to age and presence or absence of primary complex (+) and miliary tuberculosis (M).

Fig. 6 shows the three plans of combined treatment (A, B, and D) used. The dosage recommended by the M.R.C. was adhered to in all cases except the few in which toxic effects or local reactions obliged us to reduce it.

Before any patients were treated on plan D it was decided that those who had not responded adequately to a single course, as determined by the clinical state or the C.S.F., should receive the whole course, or part of it, again. Later, when relapses had been encountered, we began to give continuous prophylactic intramuscular cover to all. More recently we decided to give alternate periods of three weeks' intramuscular treatment and two weeks' rest, during which the child could go home. (These "holidays" have been welcomed by the children and their parents, not to mention the nurses, and the results so far in 6 such cases have been entirely beneficial.) Thus no limit was set to the amount of treatment that might be given on this plan; in effect, it could now be summed up as a course of combined treatment as in fig. 6 (D) with repetition of the whole or parts of the course according to progress, and prolonged continuous or intermittent intramuscular cover until the C.S.F. has been normal on two occasions in three months.

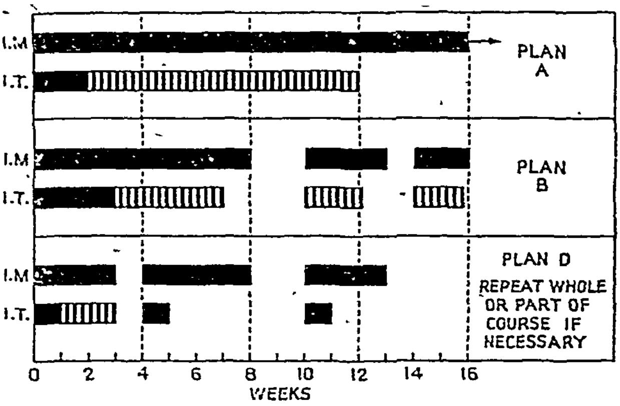

Fig. 6—Plans of combined treatment used; intrathecal injections given either daily (black) or on alternate days (barred); plan C (intramuscular treatment alone) not shown.

COMPARISON OF RHYTHMS OF TREATMENT

The response to different rhythms of treatment should not be confused with the patient's initial response. In our experience a good initial response depends mainly on early diagnosis and a free circulation in the cerebrospinal spaces. The younger the patient the more advanced is the disease likely to be and the more troublesome the mechanical obstructions to the flow of cerebrospinal fluid; but, provided that streptomycin can reach the affected tissues, a clinical response can nearly always be obtained by combined therapy in the early weeks of treatment. It is from this stage onwards that the advantage of one rhythm of treatment over another may appear.

The results of the different plans of treatment are analysed in table I. This analysis includes all cases whether they responded to treatment or not. But in trying to compare the efficacy of the different rhythms of treatment we have dealt only with cases that made an initial response (see definition) and in which the course was completed; for it is only in these that a rhythm of treatment can show its effect.

Two other cases which were eliminated from the analysis should be mentioned separately:

Case 32.—This boy died on the eleventh day from a subdural hæmorrhage due to thrombocytopenic purpura. He had miliary tuberculosis, and the thrombocytopenia was considered to be a complication of this rather than a toxic effect of streptomycin. He had not responded to treatment up to the time of his death.

Case 24.—Here intramuscular treatment alone (plan C) was given for eighteen days, and thereafter combined treatment was started because of low C.S.F.-streptomycin levels. Combined treatment was stopped after a month, but intramuscular injections were continued with rest periods. After a recrudescence, repeated courses (plan D) were given for fourteen months; finally, continuous intramuscular treatment was given for five months. After two years this child is alive and well, without sequelæ, and treatment has been stopped. His C.S.F. shows: cells 5 per c.mm., protein 55 mg., and glucose 57 mg. per 100 ml. Since the treatment has not conformed very closely to any of the given plans, particularly in the first three months, he cannot be included in any group; but we think of him as belonging to plan D.

The results with patients completing a course of treatment were as follows:

Plan	No. of cases	Surviving more than 1 year 4 mos.
A	2	2
B	7	4
D	11	8

Results of Plan A (Fig. 6)

Of the 9 patients started on this plan 7 are eliminated (cases 1, 2, 3, 6, 7, 8, and 9 in table II) because they did not complete the course. In 3 cases intrathecal treatment was abandoned after three, four, and eight weeks, and these children subsequently died. Of the other fatal cases, 1 died in less than two weeks and 3 in less than a week. Cases 4 and 5 completed the course and have fully recovered.

Case 4.—Tuberculosis of ischium. Mental state confused. Good clinical response apparent in first week. Developed spinal block after four weeks. Intrathecal treatment temporarily interrupted but resumed in twelve days when the block cleared. C.S.F. at end of four months' treatment: cells 28 per c.mm., protein 373 mg. and glucose 47 mg. per 100 ml. No further streptomycin was given. Two and a half months later, with a C.S.F. containing cells 17 per c.mm., protein 110 mg., and glucose 36 mg. per 100 ml., she was sent to a sanatorium. She was discharged from there a year and five months after the start of treatment, free from all signs of bone tuberculosis. She remains well after two years and three months off treatment. This patient did not have frequent lumbar punctures in the follow-up period as was done in later cases. Lumbar puncture a year after the end of treatment showed cells 0, protein 35 mg. and glucose 53 mg. per 100 ml.

Case 5.—Admitted in coma. Good clinical response apparent in first week. Glucose level in C.S.F. remained low for six months. Two months after the end of treatment the C.S.F. contained: cells 1 per c.mm., protein 35 mg, and glucose 43 mg. per 100 ml., a normal fluid except for the slightly low glucose level. Frequent follow-up lumbar punctures were not done. A year and two months after the start of treatment the C.S.F. showed: cells 1 per c.mm., protein 20 mg. and glucose 74 mg. per 100 ml. The patient remains well after two years and three months off treatment.

In these 2 survivors the C.S.F., though slow to return to normal, eventually did so without any further treatment. In 3 of the fatal cases (cases 2, 3, and 8), though patients developed hydrocephaly and remained stuporose and febrile, the C.S.F. trend (off treatment) paralleled that of the survivors.

Looking back on cases 4 and 5, whose complete recovery was uneventful, the C.S.F. glucose levels of 36 mg. and 43 mg. per 100 ml. at the time of their discharge were too low, and we would not happily let any of our present patients out of our hands with such a C.S.F. We thought they had had enough treatment to stamp out tuberculosis in the meninges, and that the glucose, cells, and protein in the C.S.F. would become normal in due course, as indeed they did. But in our later cases (plan D), which were given far less intrathecal treatment, a low C.S.F. glucose level at the end of the course, if not a sign of actual recrudescence was found to be almost always a precursor of deterioration unless more treatment was given. The progress of these 2 survivors suggests that, if the patient shows a good clinical response and receives combined treatment for about three months, the C.S.F. may return to normal without any more treatment. No final conclusions, however, can be drawn from 2 cases.

Results of Plan B (Fig. 6)

Of the 10 patients started on this plan, 3 are eliminated (cases 17, 19, and 25) because they did not complete the course. The clinical assessment of the 7 cases which did complete the course is as follows:

Mental state: stage 3 (coma or stupor)—none.

Miliary tuberculosis: 1 case (died).

TABLE I—RESULTS, IN SEQUENCE, OF DIFFERENT PLANS OF TREATMENT

Treatment	Plan	Cases	Mental state 3	Response to treatment	Surviving more than 1 yr. 4 mos.	Full recovery	Period covered
Combined	A	9	7	2	2	2	January, 1947, to December, 1947
	B	10	2	8	4	3	
	D	17	8	10	8	3	December, 1947 to October, 1949,
	C–D	1	0	1	1	0	
	Total	37	17	21	15 (41%)	8 (22%)	—
Intramuscular	C	6	1	2	0	0	—
	Total all plans	43	18	23	15	8	—

Among the cases followed for more than sixteen months there has been 1 death (case 12, plan B). The survival-rate for the whole group on combined treatment up to Oct. 1, 1949, is therefore 14 out of 37 (38%). All 14 are alive on Feb. 21, 1950.

Initial response: all 7 responded to treatment: 4 in the first week, and 3 after a delay of four, five, and six weeks.

Survivors: 3 cases fully recovered from meningitis. Case 10 has a residual hemiplegia and associated mental defect; cases 13 and 23 require separate mention as being exceptionally responsive to treatment.

Cases 13 and 23.—They were aged 6 and 8 years. Their mental state on admission was normal and they showed minimal signs of meningitis. X-ray films of the chest were negative. The patients responded at once to treatment, if one may describe as a response the fact that they did not deteriorate. They showed, however, a decided intolerance to intrathecal streptomycin—pyrexial peaks after the injections, severe stiffness of neck and back, pronounced Kernig reaction, and a polymorph pleocytosis in the C.S.F. So disturbing were these symptoms and so satisfactory was the patients' general condition in other respects that it was decided to omit the intrathecal injections after the first rest period; further treatment was therefore intramuscular only. Clinical and C.S.F. progress were perfect; the patients have not relapsed and are alive and well at two years and at twenty-one months after tuberculous meningitis was diagnosed.

Deaths: of the 4 fatal cases, death followed relapse in 2 and recrudescence in 2, there being no response to a second course of treatment. Case 12 is of special interest in that the relapse occurred fifteen months after the end of treatment, though for a year before the relapse the C.S.F. was slightly abnormal (see above, under discussion of relapse). Two cases had optic atrophy.

Comment: in no case which had completed the course was further treatment considered necessary at the time because of an inadequate clinical or C.S.F. response. But, if we could have been guided then by our later experience with cases on plan D, we would undoubtedly have given more treatment, even if only intramuscular, to some of these children, because of the state of their C.S.F. glucose; but we were not "glucose-minded" then as we are now.

Results of Plan D (Fig. 6)

Of the 17 cases, 6 (cases 31, 32, 36, 41, 42, and 43) died before completing the course. The clinical assessment of the 11 cases completing the course was as follows:

Mental state: stage 3 (stupor or coma)—4 patients.

Miliary tuberculosis: 4 patients (all surviving).

Initial response: all 11 patients responded to treatment, 6 in the first week, 5 after a delay of three, four, four, five, and eight weeks.

Survivors : 8 patients have survived for not less than sixteen months ; 3 have fully recovered from meningitis, though one of these (case 37), now aged 22 months, is slightly mentally retarded ; 5 patients have not yet fully recovered.

Deaths : the 3 fatal cases were as follows :

Case 33.—This patient was given a full course of plan D with half standard dosage in parts II and III because of thecal intolerance. There was steady deterioration from the start. This child is included because although she made no initial response she survived long enough for a full course of treatment to be given.

Case 27.—During eleven months in hospital and up to time of death this child's C.S.F. remained grossly abnormal. Two courses (plan D) were given because the response to the first was poor; but a month after the second course a recrudescence occurred and further treatment was without effect. Culture revealed a streptomycin-resistant tubercle bacillus (64/0·25).

Case 40.—This patient had a recrudescence six weeks after the end of one course, and deterioration was not halted by a second course.

Comment : of the 3 patients who have fully recovered, 2 showed a perfectly satisfactory clinical and C.S.F. response after one course of treatment, but both were

TABLE II—ANALYSIS OF CASES

Case no.	Age yr.	Age mos.	Mental state (stage)	Chest or other X-ray findings	Length of observation	Plan of treatment	Surviving or fatal	Latest C.S.F. of survivors			Initial response	Clinical notes
								Cells per c.mm.	Protein (mg. per 100 ml.)	Sugar (mg. per 100 ml.)		
1		11	3	PC	3 days	A	F		—		None	
2	4	5	3	PC + Mil.	3 mos.	A	F		—		None	Persistent stupor; miliary cleared
3	1		3	P.C.	11 mos.	A	F		—		None	Persistent stupor; treatment abandoned after 4 months
4	6	8	2	Bone	2 yr. 8 mos.	A	S	0	35	58 (N)	Immediate	Tuberculous osteitis of ischium healed; full recovery
5	3	5	3	Neg.	2 yr. 8 mos.	A	S	1	20	74 (N)	Immediate	Admitted in coma; full recovery
6	1	2	3	Neg.	4 days	A	F		—		None	
7	4	7	3	Neg.	3 days	A	F		—		None	
8	2	6	2	PC + Mil.	5 mos.	A	F		—		None	Miliary cleared and choroid tubercles scarred
9	1		3	PC	12 days	A	F		—		None	
10		9	1	PC.	2 yr. 5 mos.	B	S	0	30	94 (N)	Delayed	Full recovery from meningitis but with hemiplegia and mental defect; bacteriological proof lacking
11	5	8	1	PC	11 mos.	B	F		—		Delayed	Interpeduncular syndrome, blindness; recrudescence
12	5		1	Neg.	2 yr.	B	F		—		Immediate	Relapse 15 months after end of treatment
13	6	9	1	Neg.	2 yr. 4 mos.	B	S	3	5	48 (N)	Immediate	Full recovery; exceptionally responsive
14	3	10	3	PC	10 mos.	B	F		—		Delayed	Interpeduncular syndrome, partial blindness; normal C.S.F.; relapse
15	1	5	3	PC	2 days	C	F		—		None	
16		6	3	Neg.	2 days	C	F		—		None	
17	6	11	3	Neg.	2 mos.	B	F		—		None	
18	5	8	2	Neg.	1½ mos.	C	F		—		Immediate	Deterioration third week
19	1	3	1	PC	5 mos.	B	F		—		Delayed	Thalamic syndrome; treatment abandoned after 1 month; well-marked improvement 1 month later, but mental development impaired
20		11	1	PC	1 mo.	C	F		—		None	
21	2		1	PC + Mil.	5½ mos.	B	F		—		Immediate	Recrudescence; terminal measles
22	2	8	1	PC (Ca)	16 days	C	F		—		None	
23	8	11	1	Neg.	2 yr.	B	S	1	30	64 (N)	Immediate	Full recovery; exceptionally responsive
24	4	5	1	Neg.	2 yr.	C–D	S	5	55	57	Delayed	Two years' treatment required
25	1	1	1	Neg.	3½ mos.	B	F		—		None	Insidious deterioration
26	1		1	Neg.	4 mos.	C	F		—		Delayed	
27	4	9	3	Neg.	10 mos.	D	F		—		Immediate	Recrudescence; unsatisfactory progress throughout
28	5	10	1	Neg. (?)	1 yr. 9 mos.	D	S	18	55	49	Immediate	Normal C.S.F. 6 mos. after starting treatment; relapse; now doing well
29	8	11	2	Mil.	1 yr. 9 mos.	D	S	4	55	55	Delayed	Uncinate fits, lethargic encephalitis picture; partial right hemianopia and very slight ptosis in right eye; recrudescence; now very well
30	6		1	Bone	1 yr. 8 mos.	D	S	10	45	19	Immediate	Sinus mandible; recrudescence 11th month; still on treatment, with "holidays"
31	5	6	3	Neg.	1 month	D	F		—		None	
32	6	3	1	Mil.	11 days	D	F		—	—	None	Thrombocytopenic purpura; subdural hæmorrhage
33	5	3	1	PC	3½ mos.	D	F		—		None	
34	2	9	1	Mil.	1 yr. 6 mos.	D	S	4	25	56 (N)	Immediate	Recrudescence in a rest period: normal C.S.F. 11 mos. after start of treatment; then abnormal 7 mos.: now full recovery
35	1	3	1	PC + Mil.	1 yr. 6 mos.	D	S	3	60	60	Immediate	C.S.F. normal 10 mos. after starting treatment
36	2		3	PC	16 days	D	F		—		None	
37		7	1	PC	1 yr. 5 mos.	D	S	1	35	52 (N)	Immediate	Full recovery from meningitis; slight mental retardation; normal C.S.F. 9 mos. after starting treatment
38	5	6	3	Neg.	1 yr. 5 mos.	D	S	8	110	32	Immediate	Admitted in coma; developed akinesia; recrudescence twice; still on treatment
39	4	6	1	Mil.	1 yr. 4 mos.	D	S	1	35	52 (N)	Immediate	Full recovery
40	5	2	3	PC	10 mos.	D	F		—		Delayed	Unsatisfactory progress throughout
41	5		3	Neg.	1½ mos.	D	F		—		None	
42	3	3	3	Mil.	1 day	D	F		—		None	
43	2	4	3	PC	3 days	D	F		—		None	

PC, primary complex. Ca, calcified. N, normal C.S.F. Mil, miliary.

given a prolonged intramuscular course to guard against relapse. The third patient was given similar treatment, because, though he was clinically in perfect health at the end of the course, his C.S.F. still contained cells 100 per c.mm., protein 180 mg. and glucose 33 mg. per 100 ml.; after nine months' intramuscular treatment the C.S.F. reached normal and remained so.

Of the patients not yet fully recovered 4 required further courses of combined treatment because of recrudescence. One of them has weathered two such episodes. These children are still in good health, and their C.S.F. is "nearly normal," but because we are still uncertain of the significance of this state (see case 12, relapse) we have not dared to relax intramuscular cover, though their C.S.F. over a long period of observation has at times been normal. The remaining patient (case 28) is still receiving combined treatment because of a relapse after the C.S.F. had been normal, and is doing well. We are fairly confident that these children will fully recover eventually.

Discussion

In comparing the clinical condition of the patients on plans B and D it will be noted that group D was adversely weighted by 4 "advanced" cases (mental state 3), of which there were none in group B, and by 4 miliary cases as against 1 in group B. The age-distribution and the types of initial response were similar in the two groups.

In spite of these adverse factors, 8 cases out of 11 on plan D have survived for not less than sixteen months, compared with 3 cases out of 7 on plan B; and, if survival is taken as the criterion, there seems to be an appreciable difference in favour of plan D. But, if full recovery is the criterion, the results in the two groups are at present much the same, for in group D we may count 3 out of 11 as fully recovered and in group B 3 out of 7 at the end of sixteen months. However, even if we accept the evidence in favour of plan D, can we seriously adopt a scheme of treatment which may involve keeping a child in hospital with continuous or intermittent intramuscular injections and periodic bouts of intrathecal injections for one or perhaps two years (fig. 2)? A single course of treatment on plan D proved successful in 3 cases, but in our opinion this treatment must be condemned as inadequate for the majority of cases and involving a serious risk of relapse. Frequent repetitions of the course, on the other hand, may oblige us to keep the patient in hospital for an appreciable part of his childhood!

Plan B, as the results show, is also unsafe as a single course of treatment. On the basis of our later clinical experience we would undoubtedly have given these patients extended intramuscular treatment at the end of their course and might thereby have prevented the setbacks which proved fatal in 4 cases. With this addition, plan B now seems to us a promising method of treatment and better than plan D.

But now consider plan B against plan A. The only difference between these is in the rest periods. The total number of intrathecal injections is the same in both, but the inclusion of rest periods spreads out the total period of combined treatment in plan B.

The case for rest periods in a course of treatment has been presented elsewhere by one of us (Mann 1948), but we are now less impressed with their value. The child who shows intolerance to the drug, variously manifested by fever, anorexia, poor weight gain, vomiting, apathy, irritability, and sometimes meningism, derives temporary benefit from a break in treatment, but in our experience such children are few. The bulk of patients tolerate the drug fairly well, so there is little to be said for interrupted treatment. There is often an improvement in the well-being and morale of the child during a rest period, but the happiness they achieve from being spared the lumbar punctures is short-lived and they often rebel violently against further treatment. Their disappointment when the injections are renewed is often so acute that the respite is worthless. Most children after a while accept the daily lumbar punctures with pathetic resignation. Reviewing the progress of these children during the interval between one period of intrathecal injections and the next (the longest being five weeks, on plan D, fig. 6), we have not constantly found improvement either in the weight or in the C.S.F.; nor, for that matter, have we constantly found deterioration. The rest periods of a week off all treatment were too short for any significant benefit to be reflected in the weight or C.S.F.

After this experience we would prefer to discard rest periods in any future plan. Temporary intermission may be necessary for intolerance by the intrathecal route, but it is probably better to reduce intrathecal dosage in such reactors rather than break up the treatment. The elimination of the rest periods in plan B brings us back to plan A. Is this after all the best method of treatment? We have had only 2 patients who completed the course, and in a larger series we would no doubt have encountered some patients whose progress in the long run was not satisfactory. But these 2 cases have seemed more satisfactory in the end than any of the cases on other rhythms in which the initial treatment was less arduous. It is difficult to believe that any of the patients on plans B and D would have fared worse on plan A, and it seems likely that on this treatment some of their troubles would have been avoided. However, if we opt for plan A it is with the proviso that extended intramuscular cover is given after the course.

Summary of Results

Period covered by this report: January, 1947, to October, 1949.

Number of cases treated: 43. These cases were admitted between Jan 20, 1947, and June 21, 1948, a period of seventeen months.

Ages: all under 7 years, except 2 aged 8 years.

Shortest observation period: 1 year 4 months (1 case).

Longest observation period: 2 years 8 months (2 cases).

Bacteriological proof: 40 cases proved, 3 not proved (cases 9, 10, and 37).

Film positive: 47%. Culture positive: 63%. Guinea-pig positive: 88%.

Streptomycin-resistant organism in 1 case, in a relapse, sensitivity 64/0·25.

Treatment and Results

Intramuscular alone: 6 cases; surviving 0.

Combined treatment: 37 cases; surviving 14 (38%); full recovery 8 cases (22%); alive and well 6 cases; sequelæ, see cases 10 and 37 in table II and on p. 342.

The progress of all cases treated in the unit is illustrated by a survival chart, fig. 5, covering the period from January, 1947, to October, 1949. The essential clinical features of all the cases are given in table II.

Conclusions

(1) Initial response to treatment depends on a combination of several factors besides streptomycin—age, mechanical obstruction of the cerebrospinal pathways, early diagnosis, innate resistance to tuberculosis, and perhaps virulence of the tubercle bacillus—and is not greatly influenced by the manner of treatment at the start.

(2) The proportion of full recoveries in any series will depend much more on the number of initially responsive cases included than on the particular rhythm of treatment adopted.

(3) In cases showing an initial response to treatment the shortest road to full recovery for most seems to be a three months' course of combined intramuscular

and intrathecal streptomycin (with not less than 50 intrathecal injections) followed by intramuscular treatment until the C.S.F. has been normal on two occasions over a period of three months.

(4) A high proportion of survivors and ultimately of full recoveries can be obtained by giving a much shorter course of combined treatment with rest periods (plus intramuscular continuation treatment), provided this is repeated whenever the C.S.F. response is inadequate or recrudescence threatens. But this method is liable to extend treatment for well over a year and cannot be recommended in practice.

Our experience in attempting to mitigate the severity of the treatment parallels that of Dubois et al. (1949) and our conclusions are in agreement with the views of Cairns and Taylor (1949).

We wish to thank Dr. I. Doniach, department of pathology, Dr. Mary Barber and Dr. D. A. Mitchison, department of bacteriology, Hammersmith Hospital, for their collaboration in the treatment of these cases; Dr. Marc Daniels for valuable criticisms; Dr. D. G. Garrow for much assistance; Mr. S. H Moore, bacteriological technician for the Medical Research Council, the physiotherapists, and above all the nursing staff of Hammersmith Hospital for the essential part they played.

PERFORATED MECKEL'S DIVERTICULUM
BY TOMATO SKIN

J. N. Ward-McQuaid
M.B. Lond., F.R.C.S.
SURGICAL TUTOR, RADCLIFFE INFIRMARY, OXFORD

A Meckel's diverticulum is said to be present in 1–2% of people. Acute complications, however, though well recognised, are only occasionally encountered. Their variety is well illustrated by the following list of complications found at operation in the last ten years at the Radcliffe Infirmary:

Cause of acute symptoms		*No. of cases*
Acute intestinal obstruction		11
Band	6	
Intussusception	2	
Evagination through umbilicus	2	
Volvulus	1	
Peritonitis simulating appendicitis		6
Acute inflammation	3	
Inflammation and perforation	1	
Perforated peptic ulcer	1	
Perforated by foreign body	1	
Hæmorrhage from peptic ulcer		1
Total		18

The youngest patient was aged 18 days, and the oldest 75; 6 were female and 12 male. The following case emphasises the well-known need for a thorough inspection of the terminal few feet of ileum when the appendix is found to be normal in a case of suspected appendicitis.

A normal appendix was excised, no abnormality was discovered in the neighbouring organs or in the pelvis, and $2^1/_2$ ft. of the terminal ileum was found to be normal. A small pink cystic object was found free in the peritoneal cavity and was thought by the pathologist to be a twisted appendix epiploica. After operation symptoms persisted, and five days later the patient clearly had an obstruction of the small intestine.

At a second operation, by Mr. G. Cruikshank, the obstruction was found to be due to a Meckel's diverticulum wrapped round the ileum more than $3^1/_2$ ft. from the ileocæcal valve. The diverticulum was excised and the patient recovered.

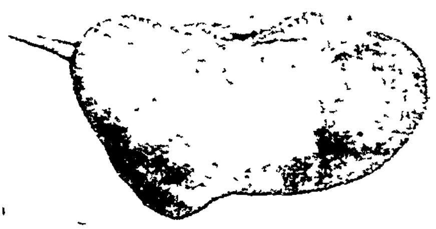
In the case of hæmorrhage from a peptic ulcer a baby, aged 8 months, had had several severe hæmorrhages from the bowel, the correct preoperative diagnosis had been made, and a Meckel's diverticulum containing a bleeding peptic ulcer was removed at operation.[1]

All of the 6 patients who died had had intestinal obstruction: 3 had been obstructed for more than two days, and in the other 3, infants under the age of $1^1/_2$ years, a resection of gangrenous gut had been necessary. The remaining 12 out of the 18 patients recovered.

The case of perforation of a Meckel's diverticulum by a foreign body, in which acute appendicitis was simulated, was most unusual and is described in detail below.

CASE-RECORD

An agricultural labourer, aged 60, was admitted to the Radcliffe Infirmary on May 25, 1949, with a diagnosis of acute appendicitis. The previous morning he had had colicky circumumbilical pain, which had gradually become worse. On the morning of admission the pain was in the right iliac fossa and the patient felt sick but did not vomit. He had had epigastric pain after meals on and off ever since a duodenal ulcer had perforated twelve years previously.



Tomato skin perforating Meckel's diverticulum.

On examination his temperature was 98°F and pulse-rate 80 per min. His tongue was furred and his breath fetid. Hyperæsthesia, muscle guarding, and release tenderness were noted in the right iliac fossa. On rectal examination there was tenderness on the right side.

Operation.—A right iliac skin-crease muscle-split incision was made under general anæsthesia. There was a little free turbid fluid in the peritoneum, but the appendix showed only serosal injection. Examination of the terminal ileum revealed a Meckel's diverticulum some $2^1/_2$ ft. from the ileocæcal valve and partly sealed off by neighbouring coils of intestine. Perforating its upper wall, near its neck, was what appeared at first to be a spike of wood, resembling the tapered end of an old yellow golf-tee. The diverticulum was excised and the ileum closed obliquely with two layers of continuous catgut sutures. The appendix was excised and the incision closed in layers with 'Nylon.' Convalescence was uneventful, and the patient was discharged eight days later.

Pathology.—The spike proved to be a piece of tomato skin, inside out, rolled to a point (see figure); it measured 4 × 3·5 cm. when spread out. The Meckel's diverticulum measured 4·5 × 1·5 × 2 cm., and its neck was 2 cm. broad. The perforation was circular and was 0·3 cm. in diameter.

Dr. J. E. French reported on the histological findings as follows: "The diverticulum appears to be lined throughout by intestinal type mucosa, and no abnormalities are seen in the wall which could account for the perforation. There is an acute inflammatory reaction in the wall at the site of the perforation, most marked on the serosal surface, where fibrino purulent material is adherent. The other coats of the wall are œdematous and show increased vascularity and a slight diffuse infiltration by round cells, polymorphs, and eosinophils. The mucosa is intact right up to the edge of the perforation."

DISCUSSION

As in the present small series, the most frequent acute complication of Meckel's diverticula is some form of acute intestinal obstruction, and the next most frequent is acute inflammation. Males are affected by these complications more frequently than females.

Perforation of a Meckel's diverticulum by a foreign body is rare, and MacFarlane[2] could find only 22 cases. These were due to a fish-bone in 15 cases, a spike of wood in 3, parts of a sewing-needle in 2, a gramophone needle in 1, and a piece of rolled tomato skin in 1. He added a case of his own, in which an inflamed diverticulum was perforated by a cabbage stalk. One reason why these perforations are much less common than the corresponding perforations of the appendix may be that the wide neck of the diverticulum allows most foreign bodies to escape. If, however, a fish-bone or a needle becomes wedged between two walls of a diverticulum its sharp point may be driven through the wall by peristalsis, as happens, for example, in the small bowel. Perforation by a blunt foreign body can be understood when the wall of the diverticulum is weakened by ulceration, inflammation, or gangrene. The foreign body may then initiate perforation, or it may merely plug a perforation already formed. Hiller and Bernhard [3] described a piece of rolled tomato skin as perforating the acutely inflamed and gangrenous wall of the diverticulum in their case. Selwyn Taylor [4] mentioned the presence of a piece of rolled tomato skin in a diverticulum removed for acute inflammation. Meckel's diverticula, however, often contain foreign bodies without any acute complication developing.

[1] Till, A. S. *Proc. R. Soc. Med.* 1949, 42, 437.
[2] Macfarlane, D. A. *Brit. J. Surg.* 1948, 35, 421.

In the present case the patient said he had last eaten tomatoes fourteen days before his admission to hospital. The blunt point of the rolled tomato skin may have been forced through the normal wall of the diverticulum by peristalsis. Alternatively, the tomato skin may have plugged a hole already made by some sharp object that was never discovered. There was no peptic ulceration to cause the perforation; and, if the wide neck of the diverticulum had been obstructed sufficiently to cause perforation, as happens in obstructive appendicitis, inflammatory changes would have been found in its mucosal wall.

I am indebted to Mr. A. Elliot-Smith for permission to publish this case; the other surgeons of the Radcliffe Infirmary for details of their cases; Dr. French, of the department of pathology, for the histological report; and Mr. R. G. Hill for the photograph.

FUNGUS INFECTION OF THE RECTOSIGMOID JUNCTION

MALCOLM S. CAMPBELL
M.B. Lond., F.R.C.S.E.
SURGEON

A. J. SHILLITOE
M.B. Lond., M.R.C.P.
PATHOLOGIST

KINGSTON GENERAL HOSPITAL, HULL

IN the case reported here the patient, who was thought to have a rectal neoplasm, was found post mortem to have had a fungus infection of the rectosigmoid junction.

A retired dock labourer, aged 63, was admitted to hospital with two months' history of loss of weight, increasing constipation with attacks of diarrhœa, and intermittent colicky pain in the lower abdomen which had become much more severe on the day before admission. His appetite was poor and he had felt nauseated but had not vomited. His bowels had opened on the night before admission and again on the morning of admission.

Previous History.—The patient had had chronic bronchitis for years. His left eye had been removed three years previously because of a radio-opaque foreign body in the eyeball.

Examination revealed a pale man of poor nutrition who looked his age, and was slightly cyanosed; temperature 97°F, pulse-rate 100, and respirations 24 per min. The tongue was dry, with a brownish coating, and there were no teeth. His blood-pressure was 240/110 mm. Hg and his pulse was regular. The abdomen was distended and tympanitic; there was some diffuse tenderness on the left side, but no guarding or rigidity, and no mass was felt. There was no visible peristalsis, and no excessive peristalsis on auscultation. The liver and spleen were not enlarged. There were no external herniæ. On rectal examination a hard irregular mass was felt on the anterior wall of the rectum, just above the prostate. The mucosa was apparently moveable on it. Apart from chronic bronchitis nothing else abnormal was found.

Progress.—Shortly after admission the patient passed a large stool. Next day his abdomen was a little distended and the descending colon was palpable and slightly tender, being filled with fæces. Plain X-ray films of the abdomen and chest were normal. On the third day after admission the patient collapsed suddenly, becoming semi-comatose, greyish in appearance, and coughing up very thick sputum. His blood-pressure had fallen to 130/50 mm. Hg, and his pulse was now irregular. No neurological abnormality was detected. He died a few hours after his collapse.

Post-mortem Findings.—The lumen of the bowel at the rectosigmoid junction was encircled and almost completely occluded for a distance of 7 cm. by what appeared to the naked eye to be a carcinomatous ulcer with very thick raised edges. There was a slight excess of fluid in the peritoneal cavity. External to the mass the bowel was adherent to the posterior aspect of the left pubic bone and to the fundus of the bladder. In the pelvic mesocolon several enlarged hard lymph-nodes were palpated, but no enlarged lymph-nodes were found in the pelvis or iliac regions. There was the scar of an old healed peptic ulcer in the pyloric antrum, but the rest of the gastro-intestinal tract seemed normal. Both lungs showed a mild chronic bronchitis, and the left was also generally congested. The left ventricle of the heart was hypertrophied, but the valves were in good condition. There was some calcification of the coronary arteries and fairly severe atheroma of the abdominal aorta. Mouth, pharynx, larynx, liver, gall-bladder, bile-ducts, spleen, pancreas, kidneys, ureters, bladder mucosa, prostate, thyroid, adrenals, pituitary, meninges, and brain appeared normal to the naked eye. The bones were not extensively examined, but there were no fistulæ or subcutaneous abscesses.

Two yeast-like bodies in granulation tissue from rectosigmoid junction. (Mallory's stain for actinomyces.) (× 310.)

Histologically, the ulcer in the rectosigmoid region showed a very dense formation of fibrous tissue in its floor and walls, with a cellular reaction of lymphocytes, plasma cells, and histiocytes. The lymphocytes tended to be arranged in small collections. Only an occasional polymorph was found, and no giant cells were present. Yeast-like-bodies were scattered throughout the lesion but were not related to the lymphoid collections. In some areas they seemed to be completely absent, but in others were fairly numerous. They stained a faint red with hæmatoxylin and eosin, and with this stain were almost indistinguishable from the surrounding tissues. When stained by Mallory's method 1 for actinomyces,[1] however, they showed up clearly as homogeneous dark-blue circular bodies (see figure), most of them 7–8 μ in diameter, some slightly larger and some smaller, and appeared to be surrounded by a refractile ring like a very thin capsule. Some of them were budding, only one bud being produced at a time. No forms with multiple buds were found. No mycelial forms were present. The circular bodies did not stain with Ziehl-Neelsen stain. Sections from several parts of the lesion all showed the same picture. There was no evidence of carcinoma or other neoplasm.

Death was attributed to hypertensive cardiac failure.

COMMENTS

The rectosigmoid junction was apparently the only site involved in this infection. It is a pity that the other organs and tissues were not examined histologically but we had been sure that the ulcer was malignant.

The specimens were fixed in formalin, so no cultural studies could be made, and it is impossible to identify the organism.

Our thanks are due to Dr. R. L. Vollum for valuable criticism and advice, and to Mr. H. Warley for the photomicrograph.

EFFECTS OF DEOXYCORTONE AND METHYLENE-BLUE IN RHEUMATOID ARTHRITIS

AN ATTEMPT TO EXPLAIN THE ACTION OF ASCORBIC ACID ON DEOXYCORTONE

LEIF HALLBERG
M.L.
ASSISTANT PHYSICIAN, COUNTY HOSPITAL, ÖRNSKÖLDSVIK, SWEDEN

THE discovery by Hench et al. (1949) of the dramatic improvement in rheumatoid arthritis produced by 'Cortisone' and adrenocorticotropic hormone (A.C.T.H.) raised great interest all over the world and stimulated extensive research in this field. The subsequent observation by Lewin and Wassén (1949) that combined treatment with deoxycortone acetate and ascorbic acid almost immediately relieves the rheumatic symptoms attracted no less attention; this treatment, if it fulfils expectations, will mean a great step forward, because deoxycortone, unlike cortisone and A.C.T.H., is a synthetic product cheaply manufactured in unlimited quantities. Further, the dosage of deoxycortone is less and the speed of action greater than those of cortisone and A.C.T.H. Hench et al. found that about 100 mg. of cortisone acetate had to be given daily; if the dosage was reduced to 50 mg. daily symptoms reappeared. Boland and Headley (1949) recommend 300 mg. the first day and then 100 mg. daily in severe cases; in mild and moderately severe cases 50 mg. daily was sufficient. Lewin and Wassén (1949) obtained good results with only 5 mg., and in some cases only 2·5 mg., of deoxycortone. Hench et al. obtained an effect in a couple of days. Boland and Headley (1949) observed improvement 6–72 hours after the beginning of the treatment with cortisone. Lewin and Wassén (1949) obtained a full effect with deoxycortone in 15–30 minutes; sometimes relief was produced as early as 5 minutes after an intramuscular injection of deoxycortone 5 mg. combined with an intravenous injection of ascorbic acid 1 g.

It is important to find out whether the interaction of deoxycortone and ascorbic acid leads to the formation of a third substance and, if so, what this substance is. There are three chief possible ways in which deoxycortone and ascorbic acid may react with each other: (1) formation of a complex compound; (2) reduction of deoxycortone; and (3) oxidation of deoxycortone. It seems most probable that ascorbic acid oxidises deoxycortone. The hormones isolated from the adrenal cortex may theoretically be regarded as oxidation products of cholesterol. On the administration of A.C.T.H. the amount of ascorbic acid and of cholesterol in the adrenal cortex is reduced (Long 1947). Apparently ascorbic acid is in some way physiologically active in the synthesis of adrenal cortical hormones.

One way to test whether ascorbic acid oxidises deoxycortone when injected in this combined treatment is to try to obtain the same clinical effect by substituting another oxidising agent for the ascorbic acid. In my experiments I used methylene-blue.

METHOD

The patients were given intramuscular deoxycortone 5 mg. and immediately afterwards intravenous methylene-blue 8 ml. of 5% solution. Controls were given either methylene-blue alone, deoxycortone alone, ascorbic acid alone, or deoxycortone and ascorbic acid according to the method of Lewin and Wassén (1949). The results were judged by the range of mobility in each joint and by the patients' ability to walk, close their hands, put their hands on their back or to the nape of their neck, and so on. The only side-effect of methylene-blue is a bitter taste in the mouth just after the injection. The patients show a pronounced cyanosis, which disappears in a few minutes. In some cases the treatment began with deoxycortone and methylene-blue, and in others with deoxycortone and ascorbic acid.

MATERIAL AND RESULTS

The method has been tried on 8 patients so far. Of these, 6 had typical rheumatoid arthritis, 1 incipient rheumatoid spondylitis, and 1 probably acute gouty arthritis (table I). In all the cases the same rapid and pronounced improvement was obtained after combined treatment with deoxycortone and methylene-blue as well as after combined treatment with deoxycortone and ascorbic acid. The rapidity of action was the same with each method, as was also the objective improvement. The effect after treatment with deoxycortone and ascorbic acid usually lasted longer than that after treatment with deoxycortone and methylene-blue, but the amount of methylene-blue injected has only about a fifth of the oxidising effect of the amount of ascorbic acid injected. The subjective improvement was equal with the two methods. The patients felt the same after the different injections, their joints were more flexible, the pains disappeared, and mobility increased. The injection of deoxycortone alone never had any effect. In most cases I observed an insignificant but undoubted objective improvement after treatment with ascorbic acid alone or methylene-blue alone. The results are summarised in table II.

TABLE I—SUMMARY OF CASES

Case no.	Sex	*Age (yr.)*	Diagnosis	Duration	Severity
1	M	57	Rheumatoid arthritis	4 mos.	Moderate
2	F	68	Rheumatoid arthritis	3 mos.	Moderate
3	F	53	Rheumatoid arthritis	9 yr.	Severe
4	F	54	Rheumaoitd arthritis	6 yr.	Severe
5	F	48	Rheumatoid arthritis	1 yr.	Severe
6	F	47	Rheumatoid arthritis	15 yr.	Severe
7	M	27	Rheumatoid spondylitis	4 mos.	Mild
8	M	35	Gouty arthritis	2 yr. (1 week)	Moderate

ILLUSTRATIVE CASE-RECORDS

CASE 1.—A timberworker, aged 57, who had earlier enjoyed perfect health, had had four months' progressive pain in several joints when he was seen on Jan. 9, 1950. He was afebrile and slightly anæmic and his erythrocyte-sedimentation rate (E.S.R.) was 20 mm. in 1 hour. Before the beginning of the experiments he could not close his left hand—the distance between the finger-tips and the palm was 1 cm. He could not put his hands on his back or to the nape of his neck; his finger-tips only reached his ears. As an example of the range of movement the left wrist was capable of dorsal flexion 30°, volar flexion 10°, and ulnar and radial deviation 10°.

Deoxycortone and Ascorbic Acid (Jan. 19).—10–12 minutes after the injections the patient felt the stiffness of the joints receding. After 30 minutes his left hand could easily be closed; his hands could easily be placed on the back of his neck and reached the ear on the opposite side; and his left wrist was capable of dorsal flexion 75°, volar flexion 60°, and ulnar and radial deviation 30°. After 36 hours the effect subsided.

TABLE II—SUMMARY OF RESULTS

Case no.	Result of therapy				
	Deoxy-cortone and methylene-blue	Deoxy-cortone and ascorbic acid	Methylene-blue	Ascorbic acid	Deoxy-cortone
1	Very good	Very good	Some effect	Some effect	Nil
2	Very good	Very good	Nil	Nil	Nil
3	Good	Good	Some effect	Some effect	Nil
4	Very good	Very good	Some effect	Some effect	Nil
5	Good	Good	Some effect	Nil	Nil
6	Very good	Very good	Some effect	Some effect	Nil
7	Very good	Very good	Nil	Nil	Nil
8	Very good	Very good	Some effect	Some effect	Nil

Deoxycortone and Methylene-blue (Jan. 23).—Before the experiment the patient could close his hand; otherwise his status was the same as before the first experiment. After 12 minutes the stiffness of his joints had diminished and the pains had disappeared. After 30 minutes the mobility was the same as after the first experiment. The patient also subjectively considered the second treatment as effective as the first one. The duration of the effect was the same.

Deoxycortone Alone (Jan. 30).—No effect.

Ascorbic Acid Alone (Jan. 28).—The range of movement of his left wrist increased somewhat. His hands, which before the injection could not reach his back, could after 30 minutes be raised to the first lumbar vertebra. The effect lasted about 6 hours.

Methylene-blue Alone (Jan. 30).—Same initial status and results as after asorbic acid alone.

Case 2.—A widow, aged 68, who had never before had any articular troubles, had in October, 1949—some weeks after an acute cholecystitis—gradually increasing pains in her ankles, shoulders, wrists, and fingers.

On admission on Jan. 25, 1950, all the fingers of her left hand were swollen. Her hand could not be closed; the finger-tips could only reach a point 2·5 cm. from the palm. She could not put her hands on her back or to the nape of her neck, or sit up in bed without assistance. Only slight changes were observed in the other joints. The patient was subfebrile and had slight anæmia. Her E.S.R. was 19 mm. in 1 hour.

Deoxycortone and Ascorbic Acid (Jan. 27).—After 15 minutes the patient could close her left hand, put her hands on her back and to the nape of her neck without difficulty, and sit up in bed without using her arms. Subjectively her joints were free from stiffness and pain. After 48 hours the stiffness recurred and the patient's condition was the same as on admission, except that she could raise herself in bed.

Methylene-blue Alone (Jan. 30).—No effect.

Deoxycortone and Methylene-blue (Jan. 31).—Before the experiment the patient's condition was the same as on Jan. 30. About 15 minutes after the injection the patient could close her hands, raise them to the nape of her neck, and put them on her back. Subjectively she considered this treatment to be as effective as the first one. The effect began to recede after 24 hours, and after 36 hours the patient could not quite close her hands, the distance between the finger-tips and her palm being 2 cm. The improved mobility of her shoulder-joints remained.

Ascorbic Acid Alone (Feb. 4).—No effect.

Deoxycortone Alone (Feb. 6).—No effect.

Case 7.—A saw-mill workman, aged 27, who had earlier enjoyed full health, had been taken ill at the beginning of October, 1949, with stiffness and pains in his back, radiating to his left leg. On Oct. 26 his illness had become acutely severe, and he was admitted to a surgical ward. At that time he could not get up from his bed even with assistance. He showed no subjective or objective symptoms of protrusion of the nucleus pulposus. Radiography of the spine and the sacroiliac joints and myelography were normal. The patient had a leucocytosis of 14,700 per c.mm. and an increased E.S.R. (36 mm. in 1 hour) which rose after two weeks to 73 mm. in 1 hour.

The patient was then transferred to a medical ward, where urography and radiography of the lungs were normal. Rectal examination revealed no tenderness over his sacro-iliac joints. Laboratory findings were normal, except for the E.S.R., which after 6 weeks had decreased to 40 mm. in 1 hour. After two months the patient was sent home for continued rest. He could then get out of his bed alone. After a fortnight he returned, showing no considerable improvement. In spite of the absence of radiological evidence of rheumatoid spondylitis, this diagnosis seemed the most probable. On examination the spine was stiff "like a board." Bending backwards and sideways was impossible; when bending forwards, the patient reached the upper edge of the patella with his fingers (40 cm. above the floor).

Deoxycortone and Ascorbic Acid (Jan. 30).—7 minutes after the injections the patient reached a point 25 cm. above the floor with his fingers, and his back felt less stiff. After 20 minutes the distance to the floor was 20 cm., and after 50 minutes 5 cm. The patient could bend low sideways and backwards without pain. 48 hours later the stiffness began to recur.

Deoxycortone and Methylene-blue (Feb. 2).—Before the experiment the patient reached a point 25 cm. above the floor with his fingers. Bending backwards was impossible, and sideways painful. 10 minutes after the injection his back felt less stiff and the pain on bending sideways had disappeared. 30 minutes afterwards the patient reached the floor with his fingers and felt as well as ever before. After 48 hours the stiffness in his back began to recur. The patient considered the second treatment to be as effective as the first.

Deoxycortone Alone (Feb. 4).—No effect.

Methylene-blue Alone (Feb. 6).—No effect.

Ascorbic Acid Alone (Feb. 7).—No effect.

DISCUSSION

If the same substance is formed when deoxycortone and methylene-blue are injected as when deoxycortone and ascorbic acid are injected, as the results suggest, this substance is an oxidation product of deoxycortone, methylene-blue being an oxidising agent.

In most cases the injection of methylene-blue alone or ascorbic acid alone had a slight beneficial effect. This can be explained by the oxidation of steroids present in the body into active substances.

The fact that the full beneficial effect is reached only if deoxycortone is given together with methylene-blue or with ascorbic acid proves that the active substance formed by the combined treatment originates chiefly from the deoxycortone.

These experiments suggest that the physiological rôle of ascorbic acid in the suprarenal glands is that of oxidising the steroids present into various active adrenal hormones.

Medical Societies

ROYAL SOCIETY OF TROPICAL MEDICINE

Chloramphenicol

THE society met on Feb. 16, under the chairmanship of Prof. H. E. SHORTT, the president, to hear a report on clinical trials of chloramphenicol by Dr. JOSEPH E. SMADEL, of the department of virus and rickettsial diseases, Army Medical Department Research and Graduate School, Washington.

Dr. Smadel described the development of chloramphenicol through the close coöperation of a number of groups of scientists in different fields. This was, he said, the first recognised naturally occurring compound produced by living tissue which contained a nitro group or which was a derivative of dichloracetic acid. Following laboratory studies and clinical trials in South America, observations on its use in scrub-typhus were made at Kuala Lumpur, Malaya.

On the day that the American group arrived, chloramphenicol therapy was instituted on a patient with typical scrub-typhus. Fever disappeared by crisis and 20 hours later the temperature was normal. Other manifestations diminished at the same time, except the primary eschar, which healed in 5 days. With further cases the duration of chemotherapy had been progressively shortened, and satisfactory results were now obtained by giving 5–6 g. over 24 hours (an initial dose of 3 g., followed by 0·25 g. at intervals of 2–3 hours). A satisfactory response had been obtained with a single oral dose of 4 g., and two other workers had employed a single 3 g. dose; but Dr. Smadel did not recommend such a procedure for general use.

There were no deaths among the hundred odd cases of scrub-typhus treated with chloramphenicol by Dr. Smadel's group, even though many of the patients were seriously ill and two were practically moribund when treatment was started. The fever disappeared in about 24 hours, and there were no complications.

Among 19 controls, 2 developed complications and 1 died; the average duration of the febrile period was 17 days.

The results of the therapeutic trials were so successful that prophylactic studies were undertaken. In the first field test, 17 out of 24 volunteers in the control group developed scrub-typhus between the 12th and 21st day after initial exposure; they were admitted to hospital and given specific therapy. The 22 members of the test groups remained well throughout the period of prophylaxis and for the following week, but a few days later 12 of them were admitted to hospital with scrub-typhus. Four further trials were carried out. The results of the third trial clearly indicated that chemoprophylaxis of scrub-typhus was feasible. To 31 volunteers 4 g. chloramphenicol was given weekly for 4 or 6 weeks after exposure to infection. Only 1 developed classical scrub-typhus during the period of administration; of the remaining 30, none developed clinical disease after the course was completed. Many, however, had mild febrile phases, during which they were found to have rickettsæmia. Whether the pronounced antigenic stimulus provided by the rickettsæmia was necessary to induce immunity was a point to be investigated further.

Dr. Smadel remarked that although the experiments indicated that chemoprophylaxis of rickettsial disease was feasible, its general usefulness was limited by practical considerations.

The possibility of immunising by inoculation with a living attenuated strain of *Rickettsia tsutsugamushi* and preventing the development of clinical disease by chloramphenicol was to be investigated.

The prophylactic trials provided new information on the host-parasite-drug relationship. This concerned the relapses that took place in about half of the 56 volunteers who had contracted scrub-typhus and had apparently responded satisfactorily to specific therapy. Such recrudescence had never been observed in patients who acquired the disease during normal occupational duties. The relapses almost always took place during the second week after onset and were promptly controlled by another course of chloramphenicol. The immediate problem was solved by giving a supplementary dose of chloramphenicol as a prophylactic measure about the time when a relapse was to be expected. Rickettsæmia unaccompanied by febrile illness was observed not only in patients shortly after treatment, but also in ambulatory volunteers during chemoprophylaxis and in volunteers shortly before onset of the initial attack or of the relapse. This observation was of fundamental importance to the understanding of scrub-typhus.

Chloramphenicol, Dr. Smadel explained, had a rickettsiostatic, not a rickettsiocidal, action; rickettsæmia, without symptoms, could persist after the drug had been administered. It was not yet possible to explain why a single dose suppressed clinical signs of disease for approximately a week. Chloramphenicol was rapidly excreted from the body and was no longer detectable in the blood 24 hours after a single dose of 3–4 g. Therefore the persistence of appreciable amounts of the native antibiotic could not explain the prolonged therapeutic effect. ‘Aureomycin’ produced the same therapeutic results as chloramphenicol in scrub-typhus; both drugs gave equally rapid defervescence.

Dr. Smadel then described the effect of chloramphenicol on typhoid fever. Here also the drug suppressed the pathogen and gave the host time to develop the mechanisms of resistance. The beneficial results in typhoid fever, however, did not become evident so rapidly as in scrub-typhus. Little effect was noted during the first two days of treatment, but by the third or fourth day the fever abated by lysis and the rose-spots, if originally present, disappeared; headache, cough, and toxæmia were ameliorated. From then onwards convalescence usually proceeded rapidly. Of 45 patients with typhoid fever who were treated with chloramphenicol during the initial phase of their illness, 44 survived.

A high relapse-rate might be expected if the drug was given for 8 days or less and few relapses if it was given for 14 days. Whilst it was still too early to set a standard schedule for the treatment of typhoid fever by chloramphenicol, the last one employed by Dr. Smadel's group in Malaya was as follows: an initial dose of 3–4 g., followed by 1·5 g. at 12-hourly intervals during the febrile period; then 1·5 g. in a single daily dose for 7 days; followed by 1 g. daily until the 14th day. More recently Dr. T. E. Woodward had given chloramphenicol in similar dosage to that described above, for the first 5 days; he then omitted the drug for 5 days; and after that he repeated the original course. He observed no relapses in 8 patients treated in this way. Dr. Smadel emphasised that chloramphenicol therapy did not eliminate intestinal hæmorrhage or intestinal perforation in typhoid. Patients still required the usual isolation precautions, but were less of a menace to public health than untreated patients.

Finally Dr. Smadel mentioned the efficacy of chloramphenicol in another rickettsial disease, Rocky Mountain spotted fever, and in venereal diseases of varied ætiology—gonorrhœa, lymphogranuloma venereum, lymphogranuloma inguinale, and syphilis. Benefits derived from its use in brucellosis and tularæmia were worth noting; and laboratory studies suggested that a number of other infectious diseases of man might be controlled by this antibiotic.

ROYAL SOCIETY OF MEDICINE

Recent Work on Vitamin B_{12}

THE society's section of experimental medicine met on Feb. 14 under the presidency of Prof. G. W. PICKERING.

Mr. E. LESTER SMITH, D.SC., described the steps by which he fractionated liver extract to obtain the anti-pernicious-anæmia factor in crystalline form. All assays had been made on man. The crucial procedures were physical rather than chemical and included adsorption on charcoal and partition chromatography. It was noticed that the active fractions were red, and this helped in following the active principle. He showed the elegant microbiological assay methods now used, and how, coupled with partition chromatography, they revealed the presence of at least three active substances: the vitamin B_{12}, an allied B_{12a}, and thymidine. He announced that from *Streptomyces griseus* he had obtained in crystalline form another substance which, tested on patients, had proved as effective as vitamin B_{12}. It had not yet received an official name, and he referred to it as “the unnamed substance.” Its chemical and physical properties were very close to those of vitamin B_{12}.

The investigation of the chemical structure of the vitamin was proceeding. One atom of cobalt was contained in its molecule; also a dimethylbenzimidazole group and probably a pyrrolic substance. On the physiological side Ternberg and Eakin[1] had lately found in normal gastric juice a non-dialysable, heat-labile substance which combined quantitatively with vitamin B_{12}; the gastric juice of patients with pernicious anæmia contained a great deal less than the normal amount of this substance. Vitamin B_{12} thus combined was not available to micro-organisms, and was more resistant to alkali and oxidative agents. It was thought that this substance might be either Castle's intrinsic factor or an important component thereof.

The cases on which Dr. C. C. UNGLEY had investigated the action of vitamin B_{12}, and some of the kindred substances isolated by Dr. Lester Smith, fell into two groups: (1) idiopathic addisonian anæmia with gastric atrophy and permanent loss of Castle's intrinsic factor, which, he said, led to deficient absorption of vitamin B_{12}; and (2) non-addisonian megaloblastic anæmias such as those associated with pregnancy and intestinal disorders, where a different mechanism was at work.

---

[1] J. Amer. chem. Soc. 1949, 71, 3858.

With a single initial dose varying from 5 to 80 µg., the actual increase of red blood-cells on the 15th day was proportional to the logarithm of the dose used; with all doses there was little effect by the 5th day, and generally after the 15th–20th day the red-cell curve flattened. In a number of cases a dose varying from 15 to 140 µg., given over a period varying from 15 to 118 days, raised the red-cell level above 4,500,000 per c.mm. For maintenance Dr. Ungley found that in the absence of subacute combined degeneration of the cord, 10 µg. every two weeks sufficed over periods ranging up to 18 months.

A system of scoring the extent of neurological defects had been worked out in 44 patients treated with liver extract for subacute combined degeneration of the cord. It had thus been possible not only to score improvements but also to establish a scale of "expected" improvement with liver extract. Of 8 patients receiving vitamin B_{12} over periods ranging from 9 to 19 months, 2 had slight, 4 moderate, and 2 severe neurological symptoms. In 4, improvement exceeded the expected rate; in 2 it attained it; and in 2 it fell just short of it. Dr. Ungley concluded therefore that vitamin B_{12} was as effective as liver extract not only in addisonian pernicious anæmia but in subacute combined degeneration of the cord. He found that weekly doses of 40 µg. were usually adequate in the first 6 months, with half that amount for maintenance. Dosage should be increased if intercurrent infection or the least sign of relapse supervened.

Lester Smith's "unnamed crystalline substance," obtained from *Streptomyces griseus*, was given to 20 cases of addisonian pernicious anæmia, 3 of them with neurological symptoms. The initial doses had proved as effective as vitamin B_{12} as regards the blood picture, glossitis, and neurological symptoms; but since no case had been treated more than three months, judgment on its final effect should be reserved. In one case a good response to the "unnamed substance" was followed by a renewed reticulocyte rise when 10 µg. of vitamin B_{12} was given.

Dr. Ungley described one patient with what seemed to be a typical addisonian anæmia (complete achlorhydria and megaloblastic marrow), who had been treated six months previously for syphilis but showed normal liver-function tests and had apparently had a satisfactory diet. His response to vitamin B_{12} was poor; but 2·5 mg. of folic acid daily (total 15 mg.) gave a satisfactory reticulocyte rise. When subsequently this patient was given 10 µg. of vitamin B_{12} of the same batch as before, at a time when the red-cell level was beginning to fall, there was a renewed rise of the level.

Even when 80 µg. of vitamin B_{12} (or of the "unnamed substance") was given *by mouth*, the response was poor. In one case 1920 µg. by mouth in 24 days gave an increase of red cells less than that expected from 5 µg. in a single injection. When in the same case 1 µg. was given by injection daily for 10 days there was a rise equivalent to what was expected of a single dose of 10 µg.

In another patient 5 µg. daily by mouth had proved ineffective. When 50 ml. of normal unfiltered gastric juice was added, there was a satisfactory response in 15 days, a total dose of 50 µg. of vitamin B_{12} resulting in a rise of red cells equal to what would be expected of 10 µg. if injected.

In yet another patient the response equalled that expected from the injection of 20 µg. One subject who took 50 µg. by mouth at one time with 500 ml. of gastric juice, reacted as he would have been expected to react to 40 µg. when injected.

Passing the gastric juice through Seitz filters removed its intrinsic-factor activity. Generally the unaccompanied oral dose needed to be about 80 times as large as the parenteral one. Dr. Ungley's efforts to determine whether gastric juice helped the absorption of vitamin B_{12} or protected it from destruction, so far left the problem unsolved.

Dr. Ungley quoted 3 cases of megaloblastic anæmia with intestinal disorder in which results were variable. One suffered from intestinal stenosis: a single dose of 80 µg. gave a response which in addisonian anæmia would have been expected from 20 µg. In another case the rise of red cells obtained with a single dose of 80 µg would have been obtained with 5 µg. A third patient, with steatorrhœa and thyrotoxicosis, was completely refractory to vitamin B_{12} but responded well to folic acid.

Six cases of megaloblastic anæmia of pregnancy were treated. Vitamin B_{12} in doses of 65–80 µg. was completely ineffective; subsequently 2·5 mg. of folic acid daily cured the anæmia and restored normoblastic bone-marrow.

Dr. Ungley insisted that vitamin B_{12} is quite as effective as liver extract in the treatment of all manifestations of addisonian anæmia; but as a reminder of how far we are from a complete solution of the physiological problem he quoted the following observation: in pernicious anæmia a remission could be brought about by giving yeast by mouth—120 g. of 'Marmite' daily. One-tenth of that dose was effective if gastric juice was given with it; and this smaller dose was all that was required in non-addisonian anæmias. Yeast extracts appeared to contain no vitamin B_{12} when tested either microbiologically or in animals; yet it seemed to act as a source of extrinsic factor.

Dr. J. V. **Dacie** reported on 30 cases of true pernicious anæmia treated with liver extract, vitamin B_{12}, and Lester Smith's "unnamed substance." It was a study of the finer relations between the histological picture of the bone-marrow, the size of the reticulocyte response, and the increase in the red cells. With a single dose of 20 µg. of vitamin B_{12} the marrow became normoblastic in the first five days, and reticulocytes might account for nearly all the red-cell increase. In some cases the marrow reverted to an "intermediate" stage as early as the 5th day and was megaloblastic by the 10th day. Dr. Dacie found that the red-cell response was biphasic, with a shelf between the 5th and the 9th day. During the second rise there were fewer reticulocytes, and almost all the increase was due to cells already mature as they reached the blood-stream. The size of the second rise depended on the dose and could be correlated with the marrow picture. A single initial dose of 30–40 µg. caused the marrow to remain normoblastic to the 15th day; 20 µg. gave a satisfactory response in the blood but allowed a regression of the marrow to the megaloblastic stage in the same period.

Dr. J. N. M. **Chalmers** said that in his clinic a maintenance dose of 20–40 µg. fortnightly had mostly proved satisfactory; in a few cases 60 µg. had been needed. In his experience vitamin B_{12} did everything that liver did; and it had proved useful in patients who had relapsed on unsatisfactory liver extract. Eight cases treated with the "unnamed substance" were doing well. Vitamin B_{12} was satisfactory in 4 patients allergic to liver extract; 1 of these, who suffered from crippling subacute combined degeneration, was restored to actively earning a living.

Dr. A. G. **Signy** reported what he thought was an effect on the bone-marrow one hour after injection in a patient in whom the marrow was studied hourly. The

PRESIDENT and Dr. P. L. MOLLISON commented on the effect of vitamin B_{12} on the survival time of transfused blood-cells which Dr. Ungley had described in some of his patients.

Hepatitis

ON Feb. 17 Prof. JOHN R. PAUL (Yale University) addressed the section of epidemiology on Endemic Hepatitis Among United States Troops in Post-war Germany. Afterwards he received the honorary membership of the section from Dr. W. H. BRADLEY, president of the section. Honorary membership has also been conferred on two other Americans—Prof. JOHN E. GORDON and Dr. JOHN GRANT.

Professor Paul began by recalling contributions to the study of hepatitis by British workers since the war. The incidence of hepatitis among U.S. troops at home had been steadily declining; the rate in Japan, which started at a relatively high figure, was also going down. But in occupied Germany the incidence had been steadily rising, until it was comparable with that in combat areas during the war—around 14 per 1000 per annum.

In the late war hepatitis "fell like a bombshell" on the U.S. Army, which was unprepared for it; preparations had been made on the lines of the 1914–18 war. First there was the outbreak of homologous-serum jaundice in 1942, due to yellow-fever vaccine. Then in 1943 came an outbreak of infective hepatitis in which the British Forces were also involved.

At least two viruses appeared to be concerned. First there was that of infective hepatitis, the naturally occurring disease; secondly, that of serum hepatitis, which was readily produced artificially. The diseases were almost the same clinically. Although the viruses were not identical, it seemed that they were of the same group. The infective type had an incubation-period as short as 15 days; contact cases were common; and the virus was found in the fæces during the acute stage and could be transmitted orally. With serum jaundice the incubation-period was 60 days; contact cases were uncommon; the virus was present in the blood during the incubation-period as well as the acute stage; and there was only parenteral infection. There was no demonstrable cross-immunity. Both diseases could be transmitted by needles. Whilst the origin of infective hepatitis was known, that of serum jaundice was not. Both infections often appeared at one time and place.

Infective hepatitis was geographically widespread, and its diffusion was aided by poor sanitary conditions. It was prevalent particularly in China, the Eastern Mediterranean, and, it seemed, Southern Germany. In the armies in North Africa and Italy there was a sharp autumnal peak: and this seasonal incidence was seen in the civilian records of Denmark and Sweden. From the civilian point of view, infective hepatitis was essentially a children's disease.

It was common in the civilian population of Germany, where little attention was paid to it. The incidence in the old Imperial German army had been twice as high in Bavaria as in Prussia. The American occupation zone of 42,000 sq. miles was composed mostly of Bavaria: and, as he had stated, the incidence of hepatitis among the U.S. occupation troops was very high. The disease occurred in the younger individuals who had been in the area a relatively short time, cases developing around the 9th–10th month of service there and being sporadic in distribution. There were slightly higher rates among troops in Berlin and Trieste. The incidence was about the same among coloured as among white troops, and bore no special relation, as in the war, to Service rank. While the British experience in Germany showed a normal seasonal swing, the incidence among the Americans showed two peaks—in October and February. This was in keeping with Ruge's observations on 'Salvarsan' hepatitis in the German navy about twenty years ago, and might possibly imply a relationship between infective and serum hepatitis.

Investigations were made to try to determine whether immunisation or the administration of penicillin could have contributed to the spread. There was some evidence that men with hepatitis had a greater penicillin history than others, but it was not completely significant and these were the men who might have got the disease by contact with German homes.

Since infective hepatitis had been endemic in the area for many years, it was not unlikely that it should be common among the occupation troops; but that it should be so common and increasing was surprising.

Prof. E. T. C. SPOONER referred to the differences between the situation in the U.S. Army in Germany and that among British troops in the Middle East in 1942–43. In the latter epidemic the incidence was higher and there was a strong seasonal trend. In the 8th Army following El Alamein, the incidence reached 15 per 1000 per month, against 14 per 1000 per year among the American Forces in Germany. A great many of the cases were widely distributed, but there were a number of units recently arrived in the area among which true explosive epidemics occurred at a time when they had been isolated from the outside world.

Dr. KLINT, of the World Health Organisation, remarked that the Royal Medical Board of Sweden had asked W.H.O. to take international action on infective and serum hepatitis. Dr. Klint wondered whether a particular type of food could have something to do with the spread. It seemed that the virus might be preserved in tinned food.

Dr. W. GUNN said that infective hepatitis was more serious in adults than in children, whereas with serum jaundice the reverse was true. He believed there were no known cases of serum hepatitis where dry serum, prepared in the L.C.C. laboratories, had been used. In measles cases they had never had any serum hepatitis, and the reason might be that 0·5% phenol was mixed with antimeasles serum. Had the use of ultraviolet radiation to inactivate serum become a practical proposition?

Dr. F. O. MACCALLUM observed that in Great Britain the incubation-period following the parenteral inoculation of volunteers with serum had never been less than 30 days. He agreed that there were probably two viruses or strains of virus, and he thought the present terminology should be changed in favour of A and B infections, as in influenza. He recalled that in a number of inoculees who had received serum from patients with presumed syringe-transmitted hepatitis, the virus had been found in nasal washings in the presymptomatic, long incubation period. He suggested that homologous-serum jaundice (hepatitis virus B) was a naturally occurring disease with a long incubation-period and a droplet spread, and that this was why it was not found ordinarily and the virus maintained itself in nature.

Dr. C. H. ANDREWES, F.R.S., postulated that in the two types of hepatitis the same virus, though of different races, might be at work.

Dr. A. M. MCFARLAN, discussing the sporadic spread and seasonal variation, said that in 1943–44, when a number of cases were reported among troops in East Anglia, only occasionally was there more than one case in a particular unit, and this unit was usually in a town where there was a civilian epidemic; it did not appear to be due to spread by contact within the unit. A very different state of affairs prevailed in divisions brought back from Scilly before D-day. There hepatitis spread through the units, with a 30-day interval between cases. In East Anglia, where hepatitis was notifiable, an abnormal season incidence was noted in 1946, when there was a rise in April which went on until August; this appeared to be an out-of-season epidemic. Apart from that one year the rise had always been in the autumn, and it had always been possible to track it down to places where there had been just a few cases during the summer; there might be a developmental cycle in the virus. This would explain many of the facts about serum hepatitis and infective hepatitis, but in this event it would be difficult to account for the lack of cross-immunity.

Dr. W. d'A. MAYCOCK referred to the results of the investigation of serum jaundice in Liverpool. It was found that the incidence in persons who had large-pool plasma (that is, from a pool made up of 300–400 donations) was 10–12%, whilst among persons who had had small-pool plasma (from pools of not more than 10 donations) it was about 0·15%. Small-pool plasma was now being produced in quantities equal to the needs of hospitals, and it was felt that this was a considerable advance in eliminating serum jaundice. Arrangements were also being made to irradiate serum.

Dr. W. M. PICKLES said that his records, going back to 1910, showed the autumnal rise. Although the virus had been discovered in the stools of infective-hepatitis cases and no-one would say it could not be transmitted in that way, Dr. Pickles thought that most cases arose by personal contact, probably droplet infection.

The PRESIDENT remarked that there had been very few cases of homologous-serum jaundice among uninoculated persons in the environment of the American soldiers affected by the yellow-fever inoculation virus. Later MacCallum, investigating some half-dozen women who developed serum jaundice following gold injection, found that the bedfellows of two of them developed hepatitis spontaneously after about 50–60 days.

Professor PAUL agreed that the terminology represented pegs on which to hang rather vague ideas that left much to be discovered. Although he had started by saying that there were two different viruses, he was rather coming round to the monotheistic point of view at the end of his paper. He did not know of any food which would harbour the disease; but that was not to say there were not some. Sterilisation of serum by ultraviolet rays was still in a somewhat experimental stage; another method was to add nitrogen-mustard to whole blood and serum; he had no experience of phenol.

He thought that Dr. Andrewes's suggestion of symbiosis was very reasonable, if only it could be proved.

LIVERPOOL MEDICAL INSTITUTION

Sudden Death in Nurslings

AT a meeting on Jan. 12, with Prof. CHARLES WELLS, the president, in the chair, Dr. F. B. SMITH said that the sudden and unexpected death of nurslings was a recurrent problem whose suggested solution often lacked conviction. The difficulties were obvious to those who performed necropsies for coroners, but were not so obvious to others. In his experience these cases formed the second largest group of sudden deaths examined for coroners, the first being disorders of coronary arteries.

The infants were usually between 4 and 40 weeks of age, and were regarded as having had normal health within a few hours, or even minutes, of being found dead. In the past smothering, overlaying, and choking by food had been the commonly accepted causes; but with an increase in the number of cases examined by necropsy an increasing proportion was being ascribed to natural causes—most often acute infections of the respiratory tract.

Necropsies on infants were often inconclusive; the naked eye was more often inadequate than in the necropsy of an adult. A set scheme was necessary, including the use of the microscope, bacteriology, histology, and, if possible, chemistry. The damage due to a wrong verdict of unnatural death might be lasting; and despite the inexpediency of delay, the proper course might be a request to the coroner for time for microscopical studies. There was need for a series of controls of the naked-eye and microscopic data often accepted as explanation of death, whether due to unnatural anoxia or acute infection.

Dr. Smith was loth to accept the view that the average nursling of this age allowed accidental smothering. Often evidence of both the presence and effect of gastric contents in the airways was questionable; for example, vomiting was a symptom of anoxia, and food in the airways was found after death from many natural causes. He was not satisfied that small infective foci in the respiratory tract or other sites, found only by the microscope, could 'explain' sudden and unexpected death. Though serosal and interstitial hæmorrhages occurred apart from obstructive anoxia, the striking flea-bitten appearance of one or all of the three organs—thymus, heart, and lungs—had not been seen in other circumstances. The possibility of chemical, allergic, or endocrine stimulus deserved consideration. Most of these infants died in the third or fourth month of life, at which time the thymus was largest in proportion to body-weight; the function of the thymus was unknown. About one-third of these infants were found to have parietal craniotabes but without clear signs of rickets.

In no more than 15 of 60 infants examined after sudden death was the opinion offered that death was due to a specific infection; and in 7 of the 15 the evidence was slender. Most often the preferable conclusion was that the cause of death was unknown.

Dr. Smith concluded with a plea for: (1) avoiding if possible an opinion based on inadequate data; (2) the use of schematic routine histology and bacteriology after death; and (3) the collection and publication of criteria for the final medical opinion on the so-called "suffocated" infant.

Reviews of Books

Estudios sobre la Circulación Renal (Barcelona: José Janés. 1949. Pp. 208. 180 Ptas).—Prof. J. Trueta's outstanding work, *Studies of the Renal Circulation*, reviewed in our columns three years ago,[1] has now been published in Spanish. It is well that this important contribution to our understanding of the medullary vessels should be easily accessible to as wide a circle of research-workers as possible. His argument is supported by convincing photographs, the beauty of which receives full justice, in this volume, from the excellent surface of the paper.

A Text-Book of Surgery by American Authors (5th ed. Philadelphia and London: W. B. Saunders. 1949. Pp. 1150. 65*s*.).—In its 5th edition this large textbook, edited by Dr. Frederick Christopher, comes fully up to what we have been led to expect. It gives an authoritative presentation of general and gynæcological surgery as nowadays practised in America. There is a great deal of new matter and there are many new authors. The book is so well known, and its reputation so high, that praise is superfluous; but it is worth considering what appeal it may have for the English. It is so complete in its range, and reflects so truly the American outlook, particularly the physiological aspects of surgery, that it will be useful to any surgeon, and especially to those who teach. Also the references at the end of each section will be helpful. Whether our undergraduates will welcome it equally is more doubtful—for two reasons. In the first place it is a very large volume for an undergraduate student to read through two or three times during the time allotted to him for clinical work: its mere size is rather appalling in prospect. Secondly, most of the contributors *assume a certain* ground knowledge of surgery which English students do not possess when they enter on their clinical stage of study. For them numerous statements would have no meaning. Take for instance the section on prostatectomy. Four methods are mentioned with their indications, advantages, and drawbacks. But what use is this if the student has no idea what is meant by the *terms* suprapubic, perineal, retropubic, or perurethral prostatectomy? The student's ignorance could be dispersed by a description in a few sentences of each operation, and he could then take an intelligent interest in the discussion. This seems a small defect in so magnificent a compilation by nearly 200 authors; yet to the undergraduate student it looms large in a book which would otherwise delight him.

THE LANCET

LONDON: SATURDAY, FEB. 25, 1950

"Suffocation" in Infancy

THE Registrar-General's returns show that in England and Wales during the five years 1943–47 no fewer than 2001 infants under one year of age were certified as having died from "accidental mechanical suffocation in bed, cot, or cradle." The tragic loss of 400 infants each year from "accidental suffocation" might seem to reflect badly on the mothers of Britain; but several investigators have concluded that such figures are unreliable, and it seems probable that most of the infants supposed to have died from accidental suffocation really died from natural causes.

DAVISON,[1] the medically qualified coroner of Birmingham, was the first to show that the true incidence of accidental suffocation in infancy is much lower than statistics suggest; and a similar conclusion has since been reached by WERNE and GARROW[2] in the U.S.A., by BOWDEN[3] in Australia, and by F. B. SMITH, whose report to Liverpool Medical Institution is summarised on another page. These authorities have made it clear that acute respiratory infections sometimes associated with acute otitis media, is much the commonest cause of death. DAVISON held that of the 210 infants in his series suspected of having died from mechanical suffocation while sleeping, only 6 had actually been suffocated. All these workers mention the need for thorough post-mortem examination in every case of sudden death in infancy; otherwise the inaccurate and distressing diagnosis of accidental suffocation is likely to be made. They also emphasise the need for careful histological examination, notably of the respiratory tract and lungs, whenever the diagnosis remains in doubt. This is important because, with a rapidly fatal course, naked-eye changes are often equivocal. Routine bacteriological investigation is also required. When a supposedly healthy infant is found dead, the parents and doctor almost always suspect suffocation; and this suspicion is strengthened when the child is found lying face downwards, as it often is. The parents' grief is deepened by remorse; and an accurate history of the child's health immediately before the tragedy can seldom be obtained from them. Almost always they fail to recollect any evidence of illness; but WERNE and GARROW, and BOWDEN, have pointed out that, if they are questioned after an interval, evidence of illness can often be elicited. Such symptoms as cough, anorexia, and lethargy had often been observed; but naturally enough these did not suggest imminent death, and at the time of the tragedy they were considered irrelevant, if indeed they were recalled at all.

Deaths from "accidental suffocation" are mostly concentrated in the first six months of life. In both Britain and the U.S.A. the peak age-incidence is in the second and third months; in the first month the incidence is much lower. This age-distribution seems incompatible with accidental suffocation, since infants are most helpless during their early weeks and have become quite vigorous by the third month. The assumption that infants are easily suffocated is untenable, for all except very young and feeble infants react vigorously to a feeling of impending suffocation and certainly do not allow themselves to be asphyxiated by turning their face to a pillow. Moreover, deaths from "accidental suffocation" have an age and seasonal incidence corresponding closely with the incidence of acute respiratory infection. The coroner should insist on a complete pathological and bacteriological investigation in all cases of suspected suffocation in infancy, in the interests not only of statistical accuracy but also of the bereaved parents; and SMITH suggests that the coroner might always be asked to grant time for histological studies. A diagnosis of accidental suffocation can amount to a life sentence of self-reproach for the parents, and it should be made only in those rare instances where the clinical and pathological evidence is incontrovertible. Coroners, of whom over 70% have no medical qualification, are usually interested only in the purely legal aspects of these cases; since there is rarely any suspicion of a criminal act, necropsy is seldom ordered, and the doctor's opinion of the cause of death is accepted. In such circumstances it would be more accurate and more humane to certify the cause of death as "unknown"—a term which SMITH thinks might be used also in the many cases where a thorough pathological examination does not reveal the cause of death.

It would be wrong to infer that reasonable precautions against accidental asphyxia are unnecessary. These should not, however, be unduly emphasised, since most mothers have an instinctive fear that their infants may suffocate; and in the U.S.A. this natural apprehension must have been greatly heightened by the publicity accorded to accounts which accept the clinical diagnosis of "accidental suffocation."[4] Some years ago the Metropolitan Life Insurance Company[5] observed that "smothering has been called the greatest hazard encountered during infancy"; and in 1945 the New York Academy of Medicine[6] launched a publicity campaign for the prevention of these "unnecessary" deaths. With very young, premature, and feeble infants, simple precautions should be taken, such as the use of a firm mattress and a thin firm pillow, and careful tucking in of the bedclothes; and with older infants great care must be taken to prevent entanglement in restraining devices, such as harness. More elaborate precautions are unnecessary, and the less said about suffocation the better.

The student's ignorance could be dispersed by a description in a few sentences of each operation, and he could then take an intelligent interest in the discussion. This seems a small defect in so magnificent a compilation by nearly 200 authors; yet to the undergraduate student it looms large in a book which would otherwise delight him.

Reconstruction of Trachea and Cervical Œsophagus

Reconstruction of the trachea would be a tough proposition even if it was commonly practised. In fact it is very seldom necessary to bridge a gap in the trachea, and little thought has therefore been given to the technique. Malignant growths of the trachea are very rare, the average surgeon being unlikely to see more than one or two in a lifetime. Such cases usually present with a severe respiratory obstruction, which is treated in the usual way by tracheotomy, but to the surgeon's surprise this does not bring relief and it becomes clear that the growth is lower down. Most of the cancers of the trachea occur in its distal part—often extending to one bronchus. The other problem which may confront the surgeon is an œsophageal or thyroid growth encroaching on, or recurring in, the tracheal wall.

The trachea is the only large tube in the body with a special structure to prevent its walls falling together; and any extensive repair must possess similar rigidity. In man, end-to-end repair after resection of more than 2 cm. of trachea is impossible, though in dogs, as **Clagett** and his colleagues[1] at the Mayo Clinic have shown, a gap involving as much as half the thoracic trachea may be thus brought together and sutured. **Clagett** has used 'Polythene' tubing with much success in dogs, but the patient in whom he used it died a week later. He has evolved a technique by which the whole of the lower third of the trachea, one bronchus and lung, plus the commencement of the other bronchus can be removed in one piece and the remaining bronchus then joined to the tracheal stump. A prepared tantalum-gauze tube with fascial sheath, as **Rob** described last year to the Association of Surgeons in Dublin, would probably be the best to use for this operation in man, though **Belsey**[2] told the same meeting of a case in which he had used fascia lata braced with a spiral stainless-steel wire for tracheal reconstruction. **Rob**'s[3] first case was a recurrence in the tracheal wall seven years after removal of a malignant thyroid. The tumour was radioresistant and invaded the anterior wall and lumen of the trachea. The operation entailed the removal of part of the cricoid, with the upper six tracheal rings, leaving a strip of membrane posteriorly only 0·5 cm. wide. The defect, which was 9 cm. long, was closed with a tube of tantalum gauze covered on both sides with fascia lata, which was carefully sutured to larynx above and trachea below. Apart from trouble through loosening of the inner layer of fascia, the patient made steady progress. The loose fascia was destroyed by diathermy after a fortnight; after 6 weeks he was discharged well, breathing normally; and, except for one area of granulation tissue 0·5 cm. square, all the gap was lined with normal tracheal epithelium. The man went back to work and was well a year later. **Rob** has extended this method to growths of the cervical œsophagus, and in one of his three cases the patient recovered, swallowing in comfort till the growth recurred 5 months later. The other two lived 4 and 5 weeks, one dying of aspiration pneumonia resulting from division of both superior laryngeal nerves. For reconstruction of the cervical œsophagus the tantalum-gauze tube is covered with fascia on the outside only. Both the gauze and fascia are removed, or extruded, within 3–4 weeks, having done their job of splinting and sealing off the reconstructed gullet till it is almost wholly lined by its new epithelium.

Several stimulating general principles are enunciated by **Rob**. Two things are required of the "bridge": (1) rigidity, permanent in the trachea, temporary in the œsophagus; and (2) a seal, provided by the ensheathing fascia lata, which prevents air or infection spreading into the tissues of the neck until they are sealed off. A layer of fascia inside the gauze is unnecessary and indeed dangerous, for it may obstruct the lumen when cast off. An important observation is that the new epithelium grows on the *inside* surface of the tantalum-gauze tube but on the *outside* of a polythene tube, the difference being due to the granulations growing through the meshes in the former. **Rob** remarks on the phenomenal speed with which the new epithelium spreads—about 10 cm. in 5 weeks. Extensive as these resections may be made, it is essential to preserve at least one recurrent and one superior laryngeal nerve; otherwise death is certain. The splint is required to stay in the œsophagus only until the epithelium has grown over the gap; so if the circumference of the epithelial lining is adequate a stricture will not form. If further experience confirms the first impressions of this method of reconstructing the cervical œsophagus it may well be better in some ways than the skin-tube method of **Mikulicz** and **Trotter**. As for the tracheal operations, these represent a bold and ingenious attempt to deal with difficulties previously considered insuperable.

THE PATIENT WITH NERVOUS FATIGUE

Tenderly cherished in the Victorian age, suspect at the turn of the century, and rudely snubbed in the 'twenties, patients with nervous fatigue are at last, if grudgingly, being allowed to sneak back into the fold of general medicine through the ever-widening psychosomatic gate. In time we may even come to admit that they don't do it on purpose. Dr. Dwight L. Wilbur has given a good deal of thought to the management of these cases, and his suggestions though not new are well stated.[1] Translating the pastoral metaphor to an active form, he finds there are three hurdles to clear: the patient must be convinced of the diagnosis; he must be relieved of his symptoms; and he must be kept largely symptom-free and preserved from relapse. With such a course before him the doctor must be willing to go into training—and first of all as a listener. Few busy doctors excel at listening, but for these cases they must bring up their reserves of attention. By listening to the patient's story they will learn more about him than he tells them, and can form a shrewd opinion of the stresses under which he is living. These may be external, related to work, wife, or family; or internal, related to a disturbance of the major emotions; or —most commonly—a mixture, partly conscious partly unconscious, of both. A sight of his home surroundings may reveal still more about him. The usual causes of nervous fatigue, in Dr. Wilbur's experience, are an

Factors in Blood-coagulation

ANYONE who tries to find his way through the recent writings on blood-coagulation may well feel confused. The difficulties and controversies have centred round the first step in the clotting process —the conversion of prothrombin to thrombin in the presence of blood-platelets and ionised calcium. Estimations of plasma-prothrombin levels are necessary for controlling modern anticoagulant therapy, and all the techniques use the formation of thrombin as an indicator; so information on the prothrombin-thrombin reaction has a practical application. In reviewing the work on blood-coagulation in 1947 we noted[1] that QUICK and OWREN had established the existence of an additional factor concerned in this reaction which QUICK called "labile factor," because it was destroyed at 58°C and was oxidised on storage, and OWREN called "factor V." There is not much of this labile factor in human plasma, but dog's plasma contains ten times and rabbit's plasma fifty times as much as man's. There have been arguments about its nature and mode of action. QUICK thought that labile factor combined quantitively with prothrombin to form thrombin; but FANTL and NANCE, SEEGERS, and WARE et al., looked on it as an accelerator of the reaction and described an "Ac-globulin" with properties very like those of labile factor.

Many of the difficulties have been solved by the use of silicone-coated apparatus in which plasma can be handled without clotting, and the differences largely disappeared when it was realised that QUICK was working with fresh human plasma whereas SEEGERS and others were using animal blood collected from a slaughter-house. Some new experiments have made possible a further step towards simplification. QUICK had already shown that a substance more or less identical with classical prothrombin can be prepared from fresh plasma by adsorption on tricalcium phosphate and can be quantitatively recovered by elution with sodium citrate; it is not certain that this substance is prothrombin, so QUICK gave it the non-committal name of "component A." QUICK and STEFANINI[2] have now shown that the more component A there is in the plasma the more labile factor is needed to attain a fixed minimal prothrombin-time. Again, when plasma which is deficient in labile factor clots, a good deal of the component A remains in the serum and is not converted into thrombin, even though thromboplastin and calcium are present in the proper concentrations; if the amount of labile factor is increased, the amount of component A converted increases proportionately. It has been known for some time that the reaction:

prothrombin + calcium + thromboplastin = thrombin

is stoichoimetric. This seems to be true also for the now modified form of the reaction:

component A + labile factor + calcium + thromboplastin = thrombin.

The next difficulty studied by QUICK and STEFANINI arose out of the old observation that the prothrombin activity of plasma increases, up to a point, when it is stored in glass containers. Since labile factor is oxidised on standing, it was necessary to add dog or rabbit plasma to show up this increased prothrombin activity. It was found that if the plasma was kept in silicone-coated vessels its prothrombin activity did not change. Further, if the component A of the plasma was isolated by the adsorption and elution technique, then the prothrombin activity of the eluate increased on storage in glass vessels but did not change in silicone-coated vessels. QUICK and STEFANINI explain this finding by postulating that component A exists in two forms: (1) a free form that exhibits prothrombin activity (i.e., is converted into thrombin in the presence of the other factors), and (2) an inactive form that cannot be converted into thrombin. When plasma is stored in contact with a relatively rough surface, such as glass, the inactive component A is converted into the free form and the "prothrombin activity" therefore appears to be increased. Hæmophilic blood contains only a trace of thromboplastinogen but its prothrombin activity is normal; the same conversion of inactive to free component A can be demonstrated in hæmophilic plasma, so thromboplastinogen is not concerned in the reaction. There is evidence suggesting that platelets and calcium also play no part in it.

We have already noted[3] that thromboplastin is thought to exist in circulating plasma in an inactive form—thromboplastinogen—which, in the presence of an enzyme derived from platelets, changes to active thromboplastin. If we call the combination of component A (free form), labile factor, and calcium the "prothrombin complex," then the steps in blood-coagulation are as follows:

(1) Thromboplastinogen $\xrightarrow{\text{platelet enzyme}}$ *thromboplastin.*
(2) Prothrombin complex + thromboplastin = *thrombin.*
(3) Fibrinogen $\xrightarrow{\text{thrombin}}$ fibrin.

The first and third reactions are enzymatic; the second seems to be definitely stoichoimetric.[4]

If these ideas are accepted, there are at least two practical consequences. One is that there are three forms of congenital "hypoprothrombinæmia": (1) the type due to deficiency of labile factor, of which OWREN's[5] case is the only one so far described; (2) the type described by QUICK,[6] apparently due to deficiency of total component A; and (3) the type previously attributed by QUICK to deficiency of "component B," but which has now been shown to be lacking only in the proportion of component A present in the free form, the total being more or less normal. The view that component A exists in two forms may explain the different values for prothrombin activity obtained by the "one-stage" and "two-stage" techniques. The one-stage method estimates only free component A; whereas the manipulations involved in the two-stage method will ensure conversion of the inactive component A to the free form, so this method will estimate total component A. It is not yet known whether the inactive component A plays any part in the coagulation reactions, or whether it acts simply as a reservoir for the free form. In the control of anticoagulant therapy with dicoumarol and related substances, QUICK's one-stage method —using thromboplastin prepared from brain tissue by his original technique—is steadily gaining adherents as the most reliable guide to significant variations in prothrombin concentration. Here, at any rate, free component A seems to be the important factor.

THE PATIENT WITH NERVOUS FATIGUE

TENDERLY cherished in the Victorian age, suspect at the turn of the century, and rudely snubbed in the 'twenties, patients with nervous fatigue are at last, if grudgingly, being allowed to sneak back into the fold of general medicine through the ever-widening psychosomatic gate. In time we may even come to admit that they don't do it on purpose. Dr. Dwight L. Wilbur has given a good deal of thought to the management of these cases, and his suggestions though not new are well stated.[1] Translating the pastoral metaphor to an active form, he finds there are three hurdles to clear: the patient must be convinced of the diagnosis; he must be relieved of his symptoms; and he must be kept largely symptom-free and preserved from relapse. With such a course before him the doctor must be willing to go into training—and first of all as a listener. Few busy doctors excel at listening, but for these cases they must bring up their reserves of attention. By listening to the patient's story they will learn more about him than he tells them, and can form a shrewd opinion of the stresses under which he is living. These may be external, related to work, wife, or family; or internal, related to a disturbance of the major emotions; or —most commonly—a mixture, partly conscious partly unconscious, of both. A sight of his home surroundings may reveal still more about him. The usual causes of nervous fatigue, in Dr. Wilbur's experience, are an emotional problem, overwork and inadequate rest, an anxiety state, constitutional inadequacy, asthenia following infection in a susceptible person, a psychotic trend, or a combination of these factors. The inclusion of overwork will interest British readers, who usually find this to be a symptom rather than a cause of nervous fatigue. Dr. Wilbur rightly holds that a thorough physical examination reassures the patient and founds his confidence in the doctor on a rock. If necessary, radiography and laboratory tests must be used to exclude disease in some organ about which the patient is particularly anxious. These investigations should be done quickly, and the negative results announced unequivocally ; the very fact of a negative finding is reassuring to the patient, even though he may be loth to believe there is nothing organically wrong. Moreover, the investigations will enlighten the doctor ; for there is always the chance that an organic lesion will be revealed by the use of these special means. When the physical examination is complete both doctor and patient will have factual evidence before them ; and the sympathetic and exact study of his symptoms will have won the patient's friendship.

Then comes the task of explaining—the first hurdle. The effects of emotion on the bodily functions are easier to accept nowadays than they used to be—thanks, perhaps, to the cinema. At all events patients will usually agree that emotion can produce loss of sleep, loss of appetite, urinary frequency, and diarrhœa ; and it is possible to lead them on to an understanding of other effects of emotion. Once they have grasped the principle, they are usually keenly interested and ask a great many questions. " The physician," Dr. Wilbur says, " must be able to have a reasonable explanation for any symptom or abnormality the patient presents." Indeed his armour of facts must be impenetrable, or he will lose his sparring contest ; what is more, his explanations must be consistent, or the patient will remember the discrepancies and lose confidence. The more ignorant —or the more intelligent—the patient, the harder it is to keep this up. He must be told definitely that in the absence of organic disease the eventual outlook for recovery is good, and warned that he will have his bad days and good days. As he begins to understand his situation, and his capacities, limitations, and frustrations, he will also begin to gain some control of his illness—at least to the extent of knowing when he must relax and acquiesce instead of fighting a hopeless battle. Those who are unable to accept the explanations, or revalue their situation to the benefit of their health, may need the help of a psychotherapist. Some general measures —diet, régime, drugs, physiotherapy, hormone treatment, or the correction of associated physical conditions, will benefit some patients. Dr. Wilbur believes that " stopping smoking will often reduce nervousness and fatigue." As for keeping the patient symptom-free—fortunately by the time he is well he has generally learned to do this for himself.

COLD IN CARDIAC PAIN

NEARLY all sufferers from cardiac pain of effort find that there is no surer way of bringing on pain than walking out in a cold wind after a meal. An effort test has been applied a good deal in studying this type of pain and the effect of exertion on the cardiogram in cases where the diagnosis is in doubt, but the experimental application of cold seems to be used only in the rather controversial " cold-pressor " test for latent hypertension. Berman and McGuire[1] have applied blocks of ice to various parts of the skin in twenty patients with cardiac pain of effort and twenty normal controls. In three of the cardiac cases this produced a depression of the S–T segment of 1 mm. in one or more limb leads. In one of these there was a greater depression of S–T when ice was applied to the nose than when it was applied to the forearm. Chest pain without cardiographic change was noted in three patients during or soon after the cold application. The controls showed some lowering of the T waves, and since the S–T intervals are not mentioned these were presumably unaffected. However, some normal people have a depressed S–T segment and an inverted T wave after exercise, and the sum of the depressions in all leads has been taken by some observers as a criterion of abnormality. There is also said to be a difference in the shape of the S–T depression between patients with cardiac ischæmia and normal people after exercise. More observations on the cold test in cardiac pain and in normal controls are needed to show whether it can be useful.

THE SICK HUMAN

HUMAN at all times, we become rather more human than usual when we are ill ; and perhaps none the more attractive for that. However, it is the business of doctors and nurses to cater for all our symptoms, even our humanness ; a duty, P.E.P.[1] think, sometimes neglected when the patient is taken into hospital. P.E.P. review, as we have often done, the ways in which hospital patients can be made to feel at home, comfortable, considered, and respected, and conversely the ways in which they can be made to feel inferior, snubbed, bewildered, and uneasy. Much turns on the spirit created by the matron, doctors, and ward sisters. A good spirit carries right through to the patient and the wardmaids—the ultimate convenient subjects for either benevolence or oppression. The caste system is still strong in our hospitals, perhaps unduly strong : " The doctor . . . is treated by the rest of the staff with a deference which seems to the outsider to be taken to absurd lengths." If he is a considerate and benevolent despot, perhaps this does not matter much ; and the same may be said of the matron. But a masterful and unimaginative matron and thoughtless or callous doctors can between them create an atmosphere in which resentful overanxious sisters, and harassed nurses, soon make the patient wish he had lingered without benefit of science in the kindly air of home. No doubt it does not happen as often as it did ; but it still happens—a hangover from the days when every patient was a charity patient, and therefore an appropriate object for bossing about.

This attitude is encouraged by the sick person's return, or partial return, to the dependency of childhood ; and it often finds expression in petty rules and restrictions. He may be kept waiting for hours in the outpatient department (though other hospitals can work a successful appointment system), he may be washed in the small hours (though other hospitals find it possible to let patients sleep till seven or eight), he may be kept in the dark about his illness and the results of investigations (though any general practitioner knows how to explain scientific facts simply and in ways that are not alarming). If the facts are too alarming, they should, in any case, be explained to relatives, but, as P.E.P. say, " the trouble is that, becoming accustomed to the infantilism of patients, doctors and nurses can easily carry over this attitude into their relationship with patients who are not so ill, and with relatives who are not ill at all." Frustrated and indignant relatives can pass their dissatisfaction on to the patient and help to delay his recovery.

Something, naturally, turns on the patient's nature. A temperamentally gifted patient may say " *I do not care how early they waked me or how often they washed me, they got me well and that is all that matters.*" But this agreeable willingness to overlook the means in favour of the end is not as common as it used to be. And perhaps the hospital hierarchy should welcome open criticism, on the same principle that good teachers welcome disputatious students: it keeps them up to the mark.

---

[1] Berman, B., McGuire, J. *Amer. J. med. Sci.* 1950, 219, 82.

[1] *Planning*, Feb. 13, p. 205. Issued by Political and Economic Planning, 16, Queen Anne's Gate, London, S.W.1.

Most of the criticisms have been met in one hospital or another: some appoint reception officers; some have appointment systems; some feed their patients well; some let them sleep late; some have a tradition of friendliness; some answer inquiries from relatives punctiliously, accurately, and at any time of the day or night; some allow visitors every evening; some ask the patient's permission before allowing his case to be taught on; and some take pains to relieve his anxiety about his state. From which it is widely argued that what some can do all can do. Yet "this overwhelming weight of opinion of outsiders," P.E.P. say, "has been ineffective in securing any change," and though this is probably too dark a view, at all events change is partial, scattered, and—by general standards—slow. A universal advance can be achieved only through people; and P.E.P. are wise to insist that much depends on the right staff, especially in high places—the right matron, the right doctors. A new service is being built up, with new people coming on to management and house committees. It is important that they should be quite free from the old notion that the patient is an object of charity: even more important that they should think of him as a fellow human—for whom the whole service is being run.

DUTCH PATCHWORK QUILT

Dr. C. Banning's Chadwick lecture on Feb. 14 dealt with the relation between voluntary effort and the State in health work in the Netherlands. In clear and colloquial English—indeed, as Sir Wilson Jameson said, "he might have been a Scot!"—*Dr. Banning dealt briefly* with health conditions in the Netherlands from the time when he became chief medical officer, direct from general practice, at the outbreak of the late war. He described the crisis period in 1944 when north Holland was completely cut off from all food-supplies and the mortality shot up steeply—infant mortality reaching 1 in 4. And in speaking of the remarkable recovery since the liberation, by which the Netherlands vital statistics have again become the envy of the world, he paid a warm tribute to Allied aid in helping recovery, illustrating Dutch gratitude with a story of a small Dutch boy who decided that God must be an Englishman. But the main point of his talk was the great part still played by the Cross organisations—the Dutch voluntary health bodies—in the public-health system. These bodies, of which the Green Cross is the largest, are responsible not only for all domiciliary nursing services but also—since their nurses are polyvalent and trained as health visitors—for public-health services and, except in the large towns, for the clinic and school services as well. Two-thirds of the population are members, paying a small graded annual fee. The result, according to Dr. Banning, is that the Dutch regard the health services as their own and not something imposed by the Hague, to be ignored or exploited. He also laid stress on the thoroughness of the midwives' training which turns them out with far more experience of normal midwifery than the newly qualified medical student possesses. Home helps have 15 months' training, and girls in general are instructed in housekeeping. The Dutch system, Dr. Banning remarked, is like a patchwork quilt, difficult to explain on paper but depending on family life and the education and cooperation of the people.

In bringing over eminent public-health administrators to lecture on various aspects of their systems, the Chadwick Trust are performing a particularly useful service.

POST-MORTEM ANGIOGRAPHY OF THE STOMACH

THE part which the vessels of the stomach play in the development of peptic ulcer has never been elucidated. Virchow, a century ago, suggested that ulcers developed as a result of embolic occlusion of end-arteries in the stomach wall. Müller and Heimberger[1] postulated a condition of "vasoneurosis," characterised by disorders of tone, permeability, and architecture of the gastric capillary-bed, which, they believed, predisposed to peptic ulceration. They examined, by direct capillaroscopy, the mucosæ of stomachs removed at operation, and found evidence of "vasoneurosis" in all of those resected for ulcer but in less than one-third of those resected for carcinoma. Other workers[2] have produced evidence that ulceration is caused by digestion of areas of mucosa rendered anæmic by muscle-spasm.

It is clearly important to develop techniques for study of the vessels of the stomach wall. The deduction by Barclay and Bentley[3] that a vascular "shunt" mechanism exists in the stomach has now been confirmed physiologically by Walder.[4] Another contribution to gastric angiography has come from Woolf,[5] who has devised two distinct methods for demonstrating respectively the arterial pattern and the capillary network. In the first the stomach is removed at necropsy together with the duodenum, pancreas, spleen, liver, and abdominal aorta en masse, and half-strength barium meal is injected with a bladder syringe through a cannula tied into a main artery. The pancreas and liver are then removed, and the stomach is opened and spread out on an X-ray plate and radiographed. By this method Woolf has demonstrated both the normal and some pathological arterial patterns. He has found tortuosity and angulation of the vessels in a patient with degenerative arterial disease, fusiform arterial dilatations in one case of malignant hypertension, and possibly spontaneous hæmorrhages in another. In a case of healed duodenal ulcer there was a poor blood-supply in the region of the ulcer (presumably due to secondary obliterative endarteritis); while in a patient with two active duodenal ulcers there were well-marked aneurysmal dilatations. With the second method the mucosal capillary pattern is demonstrated by injecting indian ink, via the gastro-epiploic artery, into a portion of stomach isolated by clamps. A 1 sq. cm. area of mucosa is dissected off the muscularis and examined by transmitted light on a microscope slide. In normal stomachs there is an irregular mucosal capillary-plexus which is broken up by the ducts of the gastric glands to give the appearance of a regular ring-like circular mesh. Vertical sections show that this plexus arises from end-arterioles, which themselves arise from a submucosal plexus. Sinus-like dilatations also arise from the end-arterioles.

Some of the features of Müller and Heimberger's "vasoneurosis" require critical examination in the light of Woolf's work. The varicosities that they described seem *identical* with the normal sinus-like dilatations which arise from the end-arterioles. The irregular capillary pattern, which was also attributed to "vasoneurosis," can be produced by simple compression of normal mucosa, and the pattern may appear to be irregular when the mucosa is atrophic and the submucosal vessels are superimposed on those near the surface. In cases of peptic ulceration Woolf has found that sometimes the stomachs show the typical features of vasoneurosis, but the vessels of others appear normal in every way.

In the further study of the vessels of the stomach in health and disease the techniques described by Barclay and Bentley and by Woolf will prove most valuable. The effects on the gastric vessels of central nervous influences and of vagal and sympathetic stimulation and inhibition deserve further investigation. When we know the relation of these factors to gastric acidity and to muscle-spasm, we may have a clearer understanding of the mechanism of peptic ulceration.

A DEATH FROM ANTISERUM

Deaths following injections of antisera are so uncommon that the odds against such a catastrophe occurring after a particular injection are 50,000 or more to 1; but they seldom escape the attention of the lay press, and, besides providing ammunition for those whose revulsion from cruelty to animals sometimes leads them to misjudge the aims and methods of experimental medicine, they may well prejudice the public against methods of treatment which are in their best interests. Lately a boy who had been bitten by his dog was given tetanus antiserum and died soon afterwards from anaphylactic shock. At the inquest it was reported[1] that he had suffered from asthma; and there seems no doubt that such people are especially liable to this risk. Even now there are more deaths from tetanus than from anaphylactic shock, and tetanus deaths could almost always have been prevented. No-one would suggest that in the present case the doctor erred in giving antiserum, and he would still have been right to give it if he had been told the history of asthma, which in fact he was not. Intradermal or conjunctival tests for hypersensitivity to serum proteins have been popular in the U.S.A., but whether they have saved any lives is doubtful. The sovereign remedy for these cases derives from sound pathology and has the support of experience. It is a sterile solution of adrenaline hydrochloride 1/1000, kept at the doctor's elbow whenever he has to administer antiserum; and some near-accidents suggest that he would be wise to see that it is in the same place when he injects vaccines and other fluids containing proteins.

LADY TATA TRUST

The Lady Tata Memorial Trust has been supporting research into leukæmia and other blood diseases for seventeen years; and a short account of the first fifteen years of the work of the international section has now been published. Financial assistance has been given to 29 workers in eleven countries in one of two ways: by short-term scholarships or expenses grants for one to three years; and by long-term expenses grants to aid experimental researches by established teams of workers. The first type of grant has supported many different researches. The second type has been used almost exclusively to support researches into animal leukæmia at centres in New York, Paris, and Copenhagen; this is regarded by many as a branch of cancer research, and the reports of the three directors confirm this view. However, as Prof. Jacob Furth points out, the development of urethane and other similar treatments for leukæmia has been greatly helped by preliminary screening tests on animals; the disease is readily transferred from leukæmic to healthy mice.

The bulk of the report is taken up by a year-to-year list of the programmes at various centres and their published work. In this country the trust has lately confined its awards to expenses grants; this is because £400 a year is now too small an income to offer an experienced worker for three years. On the other hand, an expenses grant may enable extra clerical or technical assistance to be enlisted, so furthering work already in progress. The trust has preferred to spread rather than concentrate their devalued resources.

PERIODICITY IN DISEASE

There are plenty of periodic diseases whose explanation clearly lies in the life-cycle of the infecting organism, but there are others, in which symptoms recur at fairly regular intervals for years, for no ascertainable reason, and without much disturbance of the patient's general health except during the episodes. Reimann[1] originally divided such diseases into four categories: periodic fever, abdominalgia, arthralgia, and neutropenia. Now[2] he also includes periodic purpura, thrombopenia, œdema, and urticaria, and the better-recognised syndrome of periodic paralysis. He suggests that the periodicity of these states is some justification for considering them as a single "periodic disease," of which he has seen or found references to 53 cases, 36 in males and 17 in females. The most striking uniformity of rhythm seems to occur in the cases of neutropenia, where apparently a regular cycle of about three weeks may continue for years with normal health between exacerbations; the duration of disability, with pyrexia and malaise, in these "attacks" may be only a day or two. These conditions have been thoroughly investigated without finding any satisfactory cause. Infection, allergy, endocrinological and nervous factors, and other explanations have been put forward, and Reimann thinks they are a manifestation of a basic physiological rhythm. The frequency of periodic exacerbations in disease is illustrated in our "Disabilities" series where a hæmophilic man has noted periodic variations in his tendency to bleed, a manic-depressive has described the well-recognised ups and downs in mental powers, and a man with ulcerative colitis has reported a purpuric eruption recurring every fortnight for six months. It may even be true that close scrutiny would reveal a periodicity in all chronic ailments.

PRESENT VIEWS ON TUBERCULOUS MENINGITIS

What lessons have been learnt from the three years' experience with streptomycin in the treatment of tuberculous meningitis? What was said at the UNICEF conference (summarised on p. 365), and the comments by Dr. MacCarthy and Dr. Mann on children treated under the Medical Research Council scheme (p. 341), make it clear that there is no short cut to success. Intramuscular streptomycin must be given once or twice a day for at least six months, combined with intrathecal injections for the first three months or so. The survival rate has steadily increased in the last two years, largely because cases are diagnosed sooner and treated immediately, and because the C.S.F. findings, rather than the clinical picture, are taken as the guide in deciding when the streptomycin injections can stop. Mechanical obstruction to the flow of streptomycin through the cerebrospinal pathways is a common cause of a poor initial response; administration via the ventricles or cisterna magna may solve this difficulty, but sometimes more extensive neurosurgery is required. Now that streptomycin-resistant bacilli are dispersed in the population, a resistant strain may be found at the start of treatment; so sensitivity tests are advisable throughout. Combined treatment with streptomycin and *p*-aminosalicylic acid seems to prevent sensitive strains becoming resistant, but other combinations, such as streptomycin plus 'Promizole,' or sulphones plus vitamins A and D, have their advocates, and much work is being done on new antibiotics, such as Waksman's 'Neomycin' obtained from *Streptomyces fradiæ*, to which the bacillus has not yet learnt to become resistant.

Prof. S. E. Whitnall, who had held the chairs of anatomy at McGill University, Montreal, and in the University of Bristol, died on Feb. 19 at the age of 73.

PERSONALITY AND NURSING

AN INVESTIGATION INTO SELECTION TESTS FOR NURSES

ASENATH PETRIE

MATRON

ST. GEORGE'S HOSPITAL, LONDON

IN the opinion of the Working Party on the Recruitment and Training of Nurses (1947), one in every three nurses "wasted" is unsuitable in temperament or ability and should not have been accepted for training. The Working Party added that, with the proper technique of selection, such candidates could probably be detected at entry.

A STUDY OF SELECTION TESTS

In Great Britain there are no reports of investigations designed to improve selection methods for nurses. In the United States selection tests for nurses are widely used and have reduced the wastage-rate (Sawers 1949). The tests used there at present are primarily measures of intelligence, aptitude, and educational achievement. At St. George's Hospital we have recently completed an investigation into selection tests for nurses, and as a result of it have arrived at a group of tests of personality and intelligence that we are about to use to assist us in selecting nurses for the hospital. Statistical analysis has shown that with the help of these tests we can expect to reduce the number of unsatisfactory applicants accepted at this hospital from 25 to 6%.

The investigation was planned on the assumption that personality was likely to be at least as important as intelligence in a nurse. The results lend considerable support to this assumption.

We used some of the objective measures of personality, covering various aspects of behaviour and attitude, on which considerable work has been carried out during the last few years (Himmelweit et al. 1946, Crown 1947, Eysenck et al. 1947, Petrie 1948). The plan was to find the relation between student's scores in various personality tests and her all-round performance as a nurse. It was hoped thus to arrive at a group of tests which would predict the suitability of a girl for nursing with sufficient accuracy to assist those selecting students in rejecting the majority of unsuitable candidates.

It was agreed that the official nursing examinations, though they may be an indication of whether or not a student nurse has reached the minimum academic standard required, are not an indication of the all-round performance of nurses. For example, no-one would claim that a girl who passes her examinations is ipso facto an excellent nurse; nor for that matter that those who fail may not become very good nurses. It is extremely unlikely that the actual marks on these examinations correspond to the girl's real nursing ability.

As there was no other reliable indication available of a student nurse's standing, which included her ability in the ward, the classroom, and as a member of the nursing staff of the hospital, we had to try and arrive at one. The method we finally adopted was based on rating scales; and these have proved to be reliable if certain necessary precautions are taken. It has been found also that ratings on a number of traits are more reliable than ratings on a few traits, and that the reliability of the ratings increases as the number of judges increases. By suitable statistical analysis it is possible to determine how good a measuring-rod the rating scale is, how much weight should be given to each of its items, and how reliable the judges are.

The rating scale used was devised by one of us (M. B. P.) after she had examined existing scales intended for nursing and allied professions. Nurses were rated on the following 18 personality and ability traits:

1.—Knowledge of underlying principles of nursing practice and nursing skills.
2.—Ability to adapt these to the individual needs of the patients: imagination; foresight; ability to anticipate requirements of new situations.
3.—Observation and reporting of signs, symptoms, and relevant information; accuracy; judgment; memory.
4.—General finish and smoothness of performance of clinical work; skill; accuracy, speed, and attention to detail; quietness.
5.—Care and neatness in keeping records and charts; quality of written work.
6.—Ability to rise to the occasion in emergency; initiative; resource; ability to stand up to difficult situations.
7.—Punctuality in work and in coming on duty.
8.—Reliability in carrying out assigned duties whether under supervision or not.
9.—Loyalty to the standards of the training school and the hospital; cooperation with authority; ability to accept criticism.
10.—Coöperation with other members of the ward team; influence on associates and juniors; relationship with other members of the staff.
11.—Relationship with the patients; ability to gain their coöperation; patience; understanding; kindness and sympathy.
12.—Attitude to patients' families and visitors to the ward; thoughtfulness; kindness and tact; courtesy.
13.—Ability to plan, organise, and time duties successfully; management of own work and that of others.
14.—Interest and ability in supervising work of others; instruction of patients and junior nurses.
15.—Economy in the care and use of materials.
16.—Emotional stability; poise; self-control in relation to patients and others.
17.—Appearance; general neatness and cleanliness of uniform; posture; manner.
18.—Enthusiastic interest in work of the ward or department and in learning nursing theory and practice.

Students were rated for each of these traits on a five-point scale as follows: (1) not up to standard; (2) just passable; (3) satisfactory; (4) very high; (5) outstanding. Ratings on each nurse were made by three independent judges who knew her well; these were the matron, ward sister, and the sister-tutor. The ratings were carried out after the nurses had been training for at least eighteen months to ensure that they were well known to the judges. The raters had been carefully instructed so as to avoid the main pitfalls commonly encountered.

A careful statistical analysis (including a factorial analysis) of the rating scale showed it to be comprehensive and reliable. The analysis indicated that we were justified in assessing the performance of our nurses by taking the sum of the ratings given by the three judges on each of the eighteen traits. We obtained such ratings for 126 nurses.

PERSONALITY AND INTELLIGENCE TESTS

In addition, each of these 126 nurses was given tests of personality and intelligence soon after commencing training. On the personality side we included tests of accurate observation, manual dexterity, tendency towards accuracy rather than speed in a manual task, persistence at a task, concentration, distractibility, range of interests, and degree of irritability. A word-association test was also applied; and we included a measure of the intensity of physical effort because this has been shown to be related to other facets of personality.

The intelligence tests used were of three types, measuring intelligence in a practical task (performance tests), a task involving the use of words (verbal tests), and a task involving the use of symbols (non-verbal tests).

RESULTS

Statistical analysis showed that a group of these personality and intelligence tests was closely related to the performance of the nurse as estimated by the rating scales. By using twelve of the tests that showed the closest relationship, we found it possible to predict the success of a nurse with considerably greater accuracy than we had been able to do in the past. The closeness of the relationship (multiple correlation coefficient = 0·611) compares favourably with that of the results of the Civil Service selection in this country, or with those obtained in the work that has been carried out on the selection of nurses in the U.S.A.

The practical usefulness of such a relationship can perhaps best be demonstrated in the following way. Up to the time of using the tests 70% of the applicants to this hospital had been rejected. Of the 30% selected, a quarter rated as "unsatisfactory"—i.e., they had an average rating on each trait below the "satisfactory" level of 3. If 30% of all applicants had been selected with the aid of these tests the number of satisfactory nurses would have risen from 75 to 94%. Put another way, with the aid of these tests more than three-quarters of the unsatisfactory nurses would have been eliminated.[1]

At other hospitals, where different conditions exist, the improvement in selection following upon the use of the tests will vary, depending both on the number of applications and the proportion of satisfactory nurses selected without the help of these tests. But the procedure will prove useful even where the nurses are selected from such a small group that as many as 80% of all applicants have to be accepted. The twelve personality and intelligence tests we are using take 1 hour and 6 minutes to administer, of which 56 minutes is spent in group-testing. Thus the testing of 20 nurses would take just on 4 hours.

QUALITIES OF THE GOOD NURSE

Analysis of the rating scale showed that in addition to general nursing efficiency, two separate demands were made of the good nurses—that she should have enough mental ability to cope with her work, and that she should have the kind of temperament that allows her to make the maximum use of her mental ability in this profession. Some of the tests were shown to be measuring primarily the mental ability aspects, others the temperamental aspects. For example, intelligence tests of the verbal and non-verbal types were related only to the mental ability traits, while the word-association test—a test of neuroticism—was related only to temperamental traits, and the test of manual dexterity to both sets of traits. Thus it is necessary to use a wide and varied group of personality tests in order to cover the various characteristics required of an efficient nurse.

Of the three types of intelligence tests we have used (performance, verbal, and non-verbal) only the non-verbal test is closely related to the efficiency of the nurse. Moreover, some of the personality tests were more closely related to the efficiency of the nurse than was non-verbal intelligence. For example, tendency to observe accurately, to persist in a word-building test, and to avoid mistakes in a manual task, appeared to be more closely related to success in nursing than is intellectual ability. This again emphasises the importance of not placing too much stress on intelligence tests alone in selecting nurses.

AGE AND EDUCATIONAL LEVEL

The educational status of each nurse was classified on a five-point scale, the lowest category containing those whose education had ceased at the age of 14, while the highest category contained those who had proceeded beyond the Higher Schools examination. It was found that the degree of education, in our group, was related to the success of the nurse, those in the higher categories tending to be the better nurses.

It is also of interest that there was a tendency, in our group, for the older students to be the better nurses. The age range of nurses beginning training is 18½ to 30, and it thus appears that training, as at present designed, is less suitable for the younger than for the older students.

We also found that students with fewer brothers and sisters tended to make the better nurses.

The Working Party indicated that neuroticism makes for an unsuitable temperament for nursing. It should be noted that many of the tests we have found to be most closely related to the efficiency of the nurse are also closely related to the absence of neuroticism. For example, the efficient nurse is persistent, the neurotic is not; the efficient nurse has high manual dexterity scores, the neurotic has not; and the efficient nurse has a low score on a word-association test designed to indicate neuroticism.

EXAMINATIONS

Much has been written about the desirability of changes in nursing education and in the system of examinations (Balme 1937, Bevington 1943, Working Party on the Recruitment and Training of Nurses 1947). As a slight contribution to this discussion, we mention some findings relating to the practical and theoretical examinations. We found that the relation between examination results and the performance of the nurse in hospitals, as estimated by the rating scale, was relatively low, though the practical examination gave closer results than the theoretical examination. Moreover, when contrasting the mental ability traits with the temperament traits on the rating scale, we found that the theoretical examination was related to mental ability traits only. Thus the theoretical examination is a measure almost exclusively of intellectual qualities. The practical examination was found to be related to both mental ability and to temperament traits included in the rating scale, though the relationship was not very close.

Nor was there any close relationship between the examination marks and the three types of intelligence test used. This suggests that even if we were choosing nurses solely with a view to their being able to pass examinations, we would nevertheless be ill-advised to rely on purely intellectual tests.

ATTITUDES TO NURSING

Some additional information was obtained from questionaries, in which the nurses were asked their reasons for liking and disliking nursing, their first choice of career, and so on. The answers of the 40 nurses who had been rated as the best in the hospital were compared with those of the 40 nurses who had been rated as the worst. Only those differences between the two groups which are statistically significant will be reported.

The good nurses gave more reasons for liking nursing than did the poor nurses while the poor nurses gave more reasons for disliking nursing than did the good nurses. There was a difference, moreover, in the kind of reasons given by the two groups. The good group gave more reasons for liking nursing which could be described as socially responsible—e.g., "a worth-while *job*," "it gives you a feeling of responsibility." The poor group, on the other hand, had more nurses giving as their reasons for liking nursing such things as "you are always learning," and "friendship with young people."

---

[1] These figures can be arrived at by reference to the tables of Taylor and Russell (1939).

More of the good nurses gave as their reasons for disliking nursing aspects which are not inherent in nursing, as such, and which might be altered in the future—e.g., "no warning of changes in duty," "little chance to visit home," "lack of social and outdoor life," and "not enough opportunity to treat patients as individuals." On the other hand, more of the poorer group gave as their reasons for disliking nursing aspects which seem to be *more inherent in the career itself*—e.g., "night duty," "long hours," and "examinations." These differences seem worth reporting because they are an indication that some reforms are more urgent than others if good nurses are to be retained. They also suggest that further research may disclose an even stronger association between attitudes of this type and success in the chosen profession.

The good and poor nurses were also compared with regard to their first choice of career if this was not nursing. The poor nurses had more often chosen careers which might be grouped as "exhibitionist," such as dramatic art, ballet, music, and so on; or they had chosen careers which entailed relationship with things rather than with people, such as agricultural work and librarianship. The good nurses, on the other hand, had often chosen careers entailing "humanitarian" activity, such as medicine or teaching.

It may be of interest to report another difference, though it did not reach the level of significance. The question asked was "What would you have done if you had not been accepted at a London Teaching Hospital?" To this 10·5% *more* of the good nurses than of the poor nurses stated that they would have given up the idea of nursing. This emphasises the importance of maintaining the high standard of nurses' training schools attached to teaching hospitals.

COUNSELLING AND SELECTION

The Working Party stated that "wastage comes not only from asking too much of a dull girl, but arises also from lack of appreciation of the gifts of the brighter student." These tests give considerable information about the ability and temperament of the individual nurse. It is hoped that those in charge of the nurses during their training will find this information useful in helping nurses with their difficulties.

It cannot be too strongly stressed that these selection tests are not intended to replace the interview or the study of school records, or all the other measures hitherto taken to maintain the high standard of entrants to the nursing profession. But we do suggest that selection tests should be added to the earlier selection methods because they provide additional information.

We intend to repeat the assessment of the nurses each year so that their standing at different stages in the training can be related to their scores in personality tests. We shall thus be able to improve the predictive value of these measurements.

THE LANCET Commission (1932) stated "there is evidence that shortage [of nurses] is not only quantitative but qualitative." We feel it is of prime importance to improve the qualitative selection by the use of selection tests such as have been described above. If the quality of the student nurses rises, it is likely that the whole standard of nursing will rise too: for the nurses selected will be of greater service to the patients, and at the same time the profession will become more attractive to other able young women.

SUMMARY

1. At St. George's Hospital, 126 nurses who had been in training for over six months were examined on a wide and varied group of personality and intelligence tests.

2. Ratings by three independent judges on eighteen personality traits were used to assess the all-round performance of each nurse.

3. A set of twelve of the tests were found to be closely related to the standing of the nurses (multiple correlation coefficient = 0·611). These tests included measures of accuracy of observation, concentration, tendency to make manual mistakes, persistence, and number of interests: and also included a non-verbal intelligence test, and a test of neuroticism.

4. At this hospital under present conditions, the use of these tests, in addition to the present selection procedure, would increase the number of satisfactory nurses selected from 75 to 94%. The tests would also be useful in hospitals where other conditions obtain.

5. A factorial analysis of the rating-scale suggests that, in addition to general nursing ability, two distinct sets of qualities are required of the good nurses, one depending on intellectual capacity, the other on personal relationships. Some of our measures are shown to be more highly related to one set of traits than to the other.

6. The good nurse was found to give significantly more reasons than the poor nurse for liking nursing; and significantly fewer reasons than the poor nurse for disliking nursing. The type of reason given by the two groups for these attitudes also differed.

7. The type of career which was the first choice of the good nurse differed from the type of career that was the first choice of the poor nurse.

8. Examination results were found to be closely related to neither the total rating of nursing ability, nor to measures of general intelligence.

We wish to express our thanks to the Board of Governors, and Mr. P. H. Constable, the house-governor, of St. George's Hospital, for their coöperation in arranging these investigations; to Dr. Desmond Curran, head of the department of psychiatry, for his constant help and encouragement; and to the sister-tutors, sisters, and nurses (particularly Sister Waldon-Jones), without whose coöperation this study could not have been made.

UNICEF CONFERENCE ON STREPTOMYCIN IN CHILDHOOD TUBERCULOSIS

THE International Children's Emergency Fund, in association with the World Health Organisation, has sponsored the streptomycin treatment of childhood tuberculosis, particularly tuberculous meningitis and miliary tuberculosis, in many European countries during the past year. It therefore seemed opportune to convene a technical conference of medical delegates from the countries concerned to discuss their experiences with medical experts in other countries where streptomycin has been used for the same purpose over a longer period. Most appropriately, the meetings were held in the Hôpital des Enfants Malades in Paris, under the chairmanship of Dr. ROBERT DEBRÉ, whose extensive experience in this field was again demonstrated by the contributions which he and his colleagues made on every aspect of the subject during the four-day conference from Feb. 9 to 12. The conference was organised by

Dr. Borcic, of Unicef, and it was largely owing to his efforts that the delegates completed the heavy programme within the scheduled time and went away feeling that something worth while had been accomplished. During the conference the delegates visited Brévannes, a sanatorium on the outskirts of Paris with *a unit of 70 beds for the continuance of treatment after* patients have passed the acute stages of their illness.

After the delegates from different countries had given progress reports on their work the conference settled down to discuss diagnosis, dosage, and routes of injection, indications for neurosurgery, changes in the cerebrospinal fluid (C.S.F.), the value of ophthalmoscopy and electro-encephalography, toxic and other complications, bacteriological and pathological findings, and the use of combined therapy.

DIAGNOSIS

Professor Mozziconacci (Paris), opening the discussion on diagnosis, commented on the occurrence of prodromal symptoms in over 60% of cases; in particular he had noted a subfebrile condition accompanied by fatigue and wasting and sometimes associated with a tuberculous focus in lung, pleura, or bone. In four cases tubercle bacilli were isolated from the C.S.F. before there were any localising signs and all four went on to develop meningitis. Professor Choremis (Athens), on the other hand, claimed to have isolated tubercle bacilli from the C.S.F. in cases which did not develop clinical meningitis. Fever, vomiting, headache, and constipation were the principal early symptoms of tuberculous meningitis in young children, whereas objective neurological signs such as neck-rigidity and positive Kernig sign were present in only 20% of cases. About 25% of cases were diagnosed in the first week of infection, 45% in the second week, and the rest later. When lumbar puncture, done during the course of a primary infection or miliary tuberculosis because of some neurological signs, revealed abnormalities (usually some increase in cells and protein), treatment with streptomycin was initiated by both intramuscular and intrathecal routes and was usually followed by a rapid return of the C.S.F. to normal. Such cases probably corresponded to what had been called serous tuberculous meningitis. In the subsequent discussion, attention was drawn to the value in diagnosis of the family history, a positive Mantoux reaction, and a sugar content in the C.S.F. below 45 mg. per 100 ml.

DOSAGE

Those with the longest experience—e.g., Debré of Paris, Dubois of Brussels, and Cocchi of Florence—were satisfied that the best results were obtained with *uninterrupted and prolonged treatment*, intramuscularly and intrathecally, for six months or more. Intramuscular injections (20–50 mg. per kg. of body-weight per day) were being reduced to one or two per day, with proportionately larger doses for infants than for older children. Intrathecal injections of 20–50 mg. should be given daily for some weeks and be continued at increasing intervals (three times, twice, and then once a week) until the C.S.F. returned to normal. Dr. Honor Smith (Oxford) spoke of the advantages of neurosurgery in tuberculous meningitis, and it appeared that the ventricular and cisternal routes were now being used in many centres, particularly when there were signs of spinal blockage. It was agreed that a return to normal of the cells and protein in the C.S.F. was possible during intrathecal therapy and that a cell-count below 10 per c.mm. and a sugar content over 45 mg. per 100 ml. were of greater prognostic importance than a normal protein. After return to normal the C.S.F. should be regularly examined for some months since any changes in it could give early evidence of a relapse.

CHOROIDAL TUBERCLES

An account of the appearance and significance of choroidal tubercles was given by Dr. Monbrun (Paris) on the basis of examinations in over 1000 cases of tuberculous meningitis and miliary tuberculosis. Choroidal tubercles were found in 87% of cases of miliary tuberculosis plus meningitis, in 51% of cases of miliary tuberculosis alone, and in 17% of cases of meningitis alone. Electro-encephalograms indicative of encephalitis in some cases were shown by Professor Chaptal (Paris).

BACTERIOLOGY AND PATHOLOGY

The need to establish the diagnosis bacteriologically was stressed by Prof. Robert Cruickshank (London), who recommended the inoculation by Pasteur pipette of the deposit of as much C.S.F. as could be obtained on to two tubes of Löwenstein-Jensen egg medium made with new-laid eggs. Besides its diagnostic value, repeated culture of the C.S.F. had some prognostic significance. With the appearance of streptomycin-resistant strains in the community it was becoming essential to test the streptomycin sensitivity of strains on primary isolation. For this purpose he recommended the simple procedure of direct inoculation on to egg-containing media with and without streptomycin. He spoke of the encouraging results being obtained with combined streptomycin and P.A.S. in preventing the emergence of streptomycin-resistant strains in cases of progressive exudative pulmonary tuberculosis, and thought these results had both a direct and an indirect application in the treatment of childhood tuberculosis. The pathology of tuberculous meningitis and miliary tuberculosis was discussed in detail by Professor Fanconi (Zürich) and Professor Eleftheriou (Athens).

COMBINED THERAPY

Dr. Edith Lincoln (New York) said she was obtaining very good results in both tuberculous meningitis and miliary tuberculosis with streptomycin combined with 'Promizole' by mouth in doses (0·5–1 g.) sufficient to maintain a blood-level of 1–3 mg. per 100 ml. Sulphone is demonstrable in the C.S.F. even in the absence of meningitis, and treatment with promizole is continued for three years with little evidence of side-effects except for the occasional development of secondary sex characteristics in children. It may be noted that Professor Cocchi (Florence), who gives intravenous sulphone as well as large doses of vitamins A and D, now claims over 80% cures in cases of tuberculous meningitis. However, statistics submitted by different centres could not easily be compared, and Dr. Marc Daniels (London) made a strong plea for uniformity in the recording of results of treatment. Thus, only cases treated for a year or more should be included in the report; the age of the child and the stage of the infection should be given; any selection of cases should be noted; and all deaths should be recorded. It seemed that 15–30% of all deaths still occurred in the first month of treatment; and all agreed that early diagnosis was one of the most important factors in tuberculous meningitis.

". . . An old farmer who was advised by the expert that he would shorten fattening time by adopting different feeding methods is said to have disposed of the advice with the scornful question, 'What's time to a pig, anyway?' It is easy to slip into the idea that, like the pig, the out-patient has no occasion to count the passing hours. Traditionally, if he belonged to the class for whom time was *money*, he would not (or should not) *be there. . . . But a national* service is not dealing solely with the 'sick poor' who might as well sit in a hospital waiting-room as sit anywhere else. Many who use the service will be busy people who have to plan their days as much as do doctors."—P.E.P. *Broadsheet on the Hospital Service* (II). *Planning*, Feb. 13, p. 210.

Points of View

THE CARNAGE ON THE ROADS

C. G. LEAROYD
M.R.C.S.

CHILDREN in this country are robbed of some fifty thousand years of life each year by motor traffic. Motor-cycles kill 500-1000 young men a year—twice the number of car drivers killed, though there are over four times as many cars licensed. Pedestrians, cyclists, and passengers make up well over three-quarters of the carnage. The driver of the goods vehicle has the highest average killing capacity; the private car driver comes second. The motor-bike is the most lethal form of transport; a bus can go fifteen times further before killing anybody. The ratio of killed to injured is about 1 to 30; but one or two of the 30 are economically dead.

Statistics may be convincing, but they are not so compelling as remembered scenes. We doctors in general practice collect in our memories quite a number of tragic roadside groups, snaps of crippled servitude, and cameos of homes in tears. There is always a contrasting element in them—the live animal and the pulped thing; the triviality of the error and the heavy sentence; the trip for pleasure and this. Three recent ones in my mind are: (1) a lovely English lane and a young man sprawled over a twisted motor-bike, the grey of his brain showing; (2) a nursery head and body with crushed thighs on a slab midst disinfectant smells; and (3) a dazed cluster in a cottage on the night before the inquest. We go on collecting them all our lives and can fling them in the faces of those who say: "This is an engineering or educational or legislative problem and does not particularly concern you."

Parrots say "This is a blot on our civilisation," but I am not sure that it is not part of an industrial civilisation; something of the impersonality of the machine and the ruthlessness of huge production affects its concentrated populations. The more machine-minded a nation is, the more careless of life, in that respect, it becomes; in the U.S.A. 40 million vehicles killed 32,300 people and wounded 1,150,000 in 1947.

People, however, react as strongly as ever to the isolated personal tragedy. Queen Victoria was most indignant and said that mountaineering ought to be stopped by law when Whymper left some dead friends on the Alps, but there was not any general indignation at the myriad lives halved by lead poisoning in the potteries; thousands burn with resentment at the injustice done to a Winslow boy but are left comparatively cold by "Pedestrians (under 7), 609 killed on the roads in 1948, 60·4% by goods vehicles." Most people are only capable of compassion within their own group—except in war, when the group is enlarged into the nation. This is probably defensive, for a man with a universal compassion would hardly have enough energy left to paddle out of his tears. Most doctors in their first few weeks of a job in a mental hospital feel like this.

When death, in the form of an industrial disease or a habit like gin-drinking or this road-killing, keeps stealing victims from among a moderately indifferent community, certain people with a surplus of compassion, often relatives of the victims, band themselves together and become nuclei of societies, which stimulate the Government to its duty. Eventually the Government takes on the whole job. We have not reached that stage with road casualties yet and probably will not do so for another ten years. Meanwhile the Royal Society for the Prevention of Accidents and other agencies are doing splendid work in helping to reduce the deaths, which fell from 6500 in 1938 to 4500 in 1948, though how many of the lives were saved by lack of petrol cannot be known. The individual also has his part to play, especially we doctors with our compelling pictures.

WHAT CAN BE DONE?

The problem of accident-prevention is being tackled in this country under three main headings: engineering, education, and enforcement.

Under engineering come the road schemes, the erection of a thousand signs, the robot schoolmasters of our erring feet and wheels.

"Under education, which is considered to be the main weapon in the present economic condition, a comprehensive organisation has been set up throughout the country for conducting the road-safety campaign, which was launched in 1945. Most local authorities now have their road-safety committees; the police and schoolteachers play a large part in their work of educating both children and adults in correct road behaviour."[1]

Our job here is to make instructed asides, and there is one small psychological point, probably dating back to the time when man was nomadic, which is the basis of a big proportion of road accidents—the feeling and display of superiority in those with the swifter forms of transport. You see it in the small boy with his scooter, and in primal form in the proud mien of the rider to hounds; you may remember it as an ecstasy of movement when you first took to cycling, skating, or driving a car. In others it incites envy, hatred, and admiration.

There is a simple bit of child psychology which could be turned to good account in accident-prevention education. Children and young people have a natural taste for horror stories. This is not primarily ghoulish or morbid, it is their way of learning from the experience of others. If they had to learn from their own experience there would be a terrible casualty list, and few of us would be here. The almost pleasurable apprehension of the story is kept up until it is satisfactorily topped off with an explanation or a moral, which cannot be forgotten. I remember over fifty years ago being told a satisfying story of a boy who was drowned because he ate three pounds of cherries with the stones before swimming. The modern version is: ". . . so he stepped into the road, but he was walking with the stream of the traffic and not against it, and he did not look behind him, so the Big Blue Bus . . ." Most of the children killed on the road are under seven. Cannot some genius provide them with a new set of nursery stories—*Red Riding and the Wicked Rolls*; or *Goody Twoshoes and the Bad Goods Vehicle?*

ENFORCEMENT

Excellent as all this education of children and parents is, it must cause sardonic laughter in Heaven that we train the children from earliest years and then let off the person who does the killing with half an hour's test, generally under non-testing conditions.

All that is being done for road safety now may slowly lessen the casualty list or keep it more or less stationary while the number of cars increases, but attention to the strict training of drivers would halve it in a year.

Turning a person loose with a car after the present elementary tests is like licensing a surgeon as soon as he knows the Red Cross book and how to hold a knife. Even these tests were opposed by the A.A. and the R.A.C. "They argued that tests would be of very doubtful practical utility and a source of considerable expense. They declared that the chief requisite of safe driving is 'road sense, which can only be acquired on the road itself' "[2]—i.e., by practice on the public. Yet between Nov. 1, 1946, when tests were resumed, and Nov. 26, 1949, the examiners made 976,220 tests and failed 38% of the candidates.

---

[1] Part of a letter from the secretary of the Royal Society for the Prevention of Accidents, to whom I am also indebted for many of the statistics quoted.

Tests of Fitness and Accident-proneness

The questions on the present application forms for a driving licence—Can you read so-and-so? Do you suffer from epilepsy?—are silly. The driver fills in and signs his own certificate of fitness to drive, and the person with a prohibitive but not too obvious defect has merely to lie. The only object of these questions is to cover the officials, so when the epileptic driver kills a pedestrian they can say: "We are not to blame. He signed this." It is their job to find out these things themselves—to insist on a proper medical examination, including visual and auditory tests, and an examination of past history with a right to see the panel card, besides an ordinary physical examination as for life insurance.

What a medical examination will not discover is accident-proneness. In an investigation in the U.S.A. it was found that 50% of the accidents were caused by 7% of the drivers. And the Industrial Health Research Board,[3] reporting on accident-proneness, says that if a large number of people are exposed to the same risks something like 10% of them will have 75% of the accidents. Accident-proneness, the board's report continues, is a relatively stable quality; those who have an undue number of accidents in one period of exposure will tend to do so in other periods. Further, those who have an undue number of minor accidents also tend to have an undue number of major ones.

The National Institute of Industrial Psychology devised a series of tests which can pick out the accident-prone driver. These tests are truly psychosomatic. One of them tests the time from ocular stimulus to muscular action; the lag is never less than $^3/_5$ second and the average is $1^1/_5$ seconds. Thus, with a car going at 30 m.p.h., if the driver sees a child run out in front of him, the car will move forward 26 feet before the brakes start to act with a quick-reacting driver, 53 feet with an average driver, and 80 feet with a slow-reacting driver. Other tests are for visual acuity and for judgment of spatial relationships, relative size, and speed. There is a series of tests in a dummy car with a moving picture of a road in front. The track followed by the driver and the speed attained are automatically recorded. Sir Ernest Graham-Little proposed in Parliament some sixteeen years ago that certain of these tests should be made compulsory for all applicants for driving licences, and if his advice had been taken there would be a good many more people alive today. The tests pick out the potential homicide and show others in what way they are inclined to be homicidal. There is abundant foreign experience to justify their imposition.

Lectures

Then there should be a series of lectures on Roadery and Road-craft with a written examination and a viva at the end. One lecture might well be on "Alcohol and the Driver," and, if there is merit in having insight into one's own condition, another on "The Bad Driver." I can imagine a page from the notes of a putative candidate on this:

> Over 90% of fatal accidents would not have happened if the *Highway Code* had been obeyed.
>
> Six types of bad driver:
>
> (1) *The Thruster.* Generally male. Example of male aggressiveness. Hurts his pride to be overtaken.
>
> (2) *The Hurrier.* Usually with nothing to hurry for. Associated with restlessness and acquisitiveness. (Shown aerial film of London-Brighton road on a Sunday, 50 miles of continuous traffic in which one "hurrier" overtook eight times to gain half a mile in the queue.)
>
> (3) *The Downtrodden at Home* who is a hell of a fellow behind ten horse-power.
>
> (4) *The Dreamer.* You cannot see mental pictures and real ones clearly at the same time. Malcolm Campbell's definition of a good driver: "Concentration and again more concentration. Your mind must not wander for a second."
>
> (5) *The Speed Merchant* who enjoys speed for its own sake. Generally immature. Speed is the biggest single factor in fatal accidents.
>
> (6) *The Exhibitionist.* The man or youth who wants others to think he is a dare-devil.

Anyone who thinks that road-craft consists in sitting behind a wheel and steering is on a par with those who think all a judge has to do is to dress up and look wise. Road-craft requires the skill of a cricketer, the intuitions and knowledge of conventions of the bridge player, and the imperturbable patience of a dry-fly man.

The tests of accident-proneness and lectures on road-craft should be given also to the children of 14–15 at school, where Roadery and Road-craft should rank with the three Rs. Boys have a natural aptitude for these subjects, and embryo drivers would thus start their training early. In any case, safety on the road affects them vitally: "It is estimated that at the present rate every fourth or fifth child born in Great Britain is destined to be killed or injured in a road accident."[4] The *Highway Code* might be learnt by heart, as the Catechism used to be, or set to music.

Then to the actual driving test on the road should be added a dusk and night test; dusk is a peak hour for killing and it is absurd to let a driver loose until he has been tested in it.

There is also much to be said for laying out special tracks for testing drivers. London omnibus drivers have or had one and part of it was greased, so that they could practise rectifying skids. With india-rubber children and dogs scudding about, operated from a central control tower, and with other delights, it could be made a real test for a driver's reaction to emergency conditions.

Some years ago I admitted to a mental hospital a young woman with acute hysteria, who had just killed a bread-winner cycling home in the dusk. Whatever the merits of the accident—and there were no witnesses—I am absolutely certain she should not have been a driver. In the proposed course she would have failed on past history, in the medical examination, in the body-mind tests, probably in the written examination and viva, and certainly over the emergency track. She had passed the usual test.

A word must be said about the motor-bikes, which are the most lethal instruments on the road. Unless the tester rides pillion it is impossible to make the driving test for motor-cyclists a real one, and therefore it is all the more necessary to make the rider's factual knowledge as complete as possible. It is just murder allowing these boys of 16 to go on the road without letting them know what they are in for. They are, however, at an age when, though the sense of adventure is at its strongest, a wise nature has also quickened their sense of self-preservation, which expresses itself as a love and memory for horrors, warnings from vicarious experience. The lectures to them would be on these lines:

> "You may get a grand thrill going round a bend at 60 m.p.h. and banking at 60°, but just remember what you may be running into—the greasy patch and the skid, sheep, the car on the wrong side, playing children."
>
> Then follow a dozen short films of real motor-bike smashes —the roadside confusion, the twisted metal shorn of glory, close-up of the stertorous head, the ambulance, a glimpse

through a door at a sheeted figure, the glimpse that does not disclose finally but suggests endlessly.

"If you want to be bold and bad, go and do it in the boxing ring or on the football field or on a horse. Only 23 people were killed in these ways last year, whereas on motor-bikes there were . . ."

At the end of the courses for drivers and riders, when they were handed their licences, they would be given a little slip telling them—quite cheerfully—that the most dangerous time for them would be not when they first went on the road but shortly afterwards, when the caution of the novice had worn off.

The whole course would take about ten days, and a driver's licence would be on a par with a pilot's certificate, and as worth guarding as a minor professional qualification.

Any motoring offence, especially exceeding the limit on restricted roads, where two-thirds of the deaths occurred last year, should automatically involve a testing or re-testing. This would make the old driver who was uncertain of passing the test extraordinarily careful. It would also threaten the livelihood of the careless goods-vehicle driver, who is the biggest killer of children. This should be made mandatory on our amateur justices, the bulk of whom are drivers themselves and can be lenient to the point of flabbiness.

CONCLUSION

The whole question is this: Having regard to the facts that 4500–5000 people are killed and some 150,000 wounded on the roads each year and that 90% of these accidents are preventable, is driving a sufficiently lethal occupation to demand skilled drivers who are adequately tested?

Whether the Minister of Transport and a Parliament of drivers are brave and selfless enough to do anything about it is another matter.

Meanwhile twelve people going about their tasks today are destined to be killed on the roads tomorrow.

Public Health

Supplies of B.C.G. Vaccine

ACCORDING to an announcement by the Department of Health for Scotland, "reports and letters appearing in the press indicate that there is a belief that the temporary stoppage of supplies of B.C.G. vaccine is due to financial reasons.

"This belief," says the announcement, "has no foundation. As has been previously stated, the stoppage is entirely due to production difficulties of a technical nature. Everything possible is being done to overcome these difficulties, and the Department of Health hope that as a result further supplies of B.C.G. will be available in the near future."

Scottish Report on Poliomyelitis

In a report on the 1947 epidemic of poliomyelitis, the Department of Health for Scotland notes that the disease seemed to attack small, rather than large, family groups; and "it was obvious that poliomyelitis was a disease especially of persons living in four apartment houses, particularly those with less than six occupants." Compared with previous years, there was a significant increase in the percentage of cases among people over 15 years of age. In the 1947 epidemic, 6·5% of cases were among children under 1 year of age, 35·8% among those aged 1–4 years, 34·6% among those aged 5–14 years, and 23·1% among people aged 15 years or more. Paralytic poliomyelitis was a disease principally of the cities. The focal attack of the outbreak in cities was in children under 5 years of age, whereas in rural areas it was in older patients.

Estimate of Births

The Registrar-General's return for the week ended Feb. 4 gives the following estimates for live births in England and Wales: final estimate for the quarter ending March 31, 186,000; provisional estimate for the quarter ending June 30, 183,000.

In England Now

A Running Commentary by Peripatetic Correspondents

I HAVE been following the activities of my colleagues, and others who are offering themselves at the hustings, with purely academic interest, because, like everyone else, I made up my mind which way to vote before the campaign had even started and quite irrespective of the candidates' oratorical powers. I have been sadly disappointed at the low standard of repartee in dealing with hecklers, which is perhaps attributable to the modern habit of politicians of haranguing defenceless audiences over the wireless. Such retorts as "Shut up!", "Oh *do* shut up!", and "You silly woman" represent a stage in the development of repartee that most of us left behind at our prep-school and are asking for the radio rejoinder: "You clot!"

There seems to be a lack of subtlety and originality in the posters, too. When Lord Addison was standing in the 1910 election his opponent put up a poster saying: "Dr. Addison asks for support on the ground that he is used to cutting up bodies. Will you let him cut up the Empire? Don't vote for Addison who Cuts Up the Stomach, but vote for Hay who will See it is FILLED." People (including the Editor of *The Lancet*) wrote to the *Daily Chronicle* about it. You can read the angry headlines in the faded cuttings in that fascinating store of medical miscellanea, the scrap-books in the Royal College of Surgeons library in London. I fancy that one of the attractions of electioneering is that sticking up posters for passers-by to see gives vent to a primitive urge. There is surely the same underlying motive in sticking slogans on outdoor walls at election times and in scribbling other things on other walls at other times.

* * *

My wife has undertaken to distribute milk to the more needy coloured infants at what may be called a welfare clinic in the grounds of our excellent maternity unit. The maximum age is about three years. Since she started this I have often been surprised to hear smatterings of pidgin-Arabic floating round the house, to the amusement of the servants, because with commendable enterprise my wife took on the job not knowing much more than *imshi* and the more useful *fissa*.

In my own ignorance I had carefully explained to her that a certain amount of organisation was needed if she was to make up, distribute, and annotate the issue of milk to upwards of fifty screaming infants whose escorts had never learnt the art of queueing. The maths involved in mixing dried milk with water, being psychic as to the number who would turn up, and opening sufficient tins in advance occupied more than one whole evening.

We need not have worried. All our planning went by the board. The children appeared with escort—usually some relative about a year older than the eldest child taking part in this new whim of the mad British. Sometimes the escorts would appear without infants but with filthy bottles in lieu, so the order went out: "No chicos, no milk." On the next few mornings the provision of "chicos" was accomplished with such speed that the only honest explanation could have been that all the "patients" lived just outside the hospital compound.

The proceedings are enlivened by the occasional appearance of the clinic doctor—a very hard-worked lady—whose method of communication can at least be said to quell the riot for a few seconds. She resorts to a flow of language, pitched in a voice even higher than that of the indigenous population, which leaves all mute and gaping with awe. The method adopted by one of the interpreters, who gave a helping hand the first few mornings, is equally effective; this consists in beating a rapid tattoo with both hands on the heads of all children in reach. The milk is distributed in emptied butter tins, and woe betide the doler-out-of-milk if, in a fit of temporary aberration, she hands out an Australian butter tin when a South African one was handed in. The very small infants are given bottles—with careful instructions as to which is the teat and which the valve. The finest sight of all is the row of babies lying on their backs on narrow benches swigging down their half pints like old topers.

* * *

The Society of Applied Omphaloscopists held its winter meeting at the Pavilion at Brighton. The programme, intellectual, social, and nutritional, could not have been bettered, and it was worth a lot to see the doyen of the society deliver his fervent address while giving fearful glances over his shoulder at the serpents and cockatrices on the walls which seemed likely to attack *a tergo*. To secretaries of similar bodies I recommend the Pavilion. There is space for man and motor-car, catering above the average—and Brighton. Of all towns in this country it has most of that gaiety which is sometimes called "Continental." (Have you ever been in Rennes on a wet Monday evening?) But these conventions of learned and less learned societies are becoming a major problem. Few medical schools can deal with an attendance of several hundred, and hotel accommodation in many towns is insufficient. Our colleagues in the U.S.A. take one or more hotels entire, and that method, or some coöperation with Mr. Butlin, might be explored here. Wouldn't the provision of accommodation offer an escape from penury to one or more noble dukes? Bed and board for a few hundred, with lectures in the ballroom and dinner in the banqueting-hall, should not be too difficult, and at the rate at which we doctors form congregations of common interest the palace might be let for ten months out of twelve. The row of Lelys or Gainsboroughs would look better on the wall than those dusty anatomical charts.

* * *

I'm not much of a one for Old So-and-So's gatherings, and I have only been to one Old Boys' dinner since I left school in 1921 (great scot! It's nearly thirty years). I went to last night's one to see Norman, a life-long though intermittent friend, and the secretary knew this, but of course he put us in opposite corners of the room, blast him. My neighbours were (*a*) a rugger enthusiast, real or simulated, who somehow recalled that I was in the XV (as 15th man) and therefore assumed that I knew and cared how the school was doing this season; and (*b*) a man who mistook me for my elder brother and regaled me with reminiscences of friends whom I had never known. But these were at least decent looking old boys (as distinct from Old Boys). What shocked me were the glimpses I kept getting of my real school friends hidden behind the battered ruins of a human face. Sometimes a trick of expression or typical gesture would give them away. Or someone would ask: "Isn't that old X over there?" Then I would realise that this fat bald puffy-cheeked debauchee was indeed all that remained of my study-mate, lively and lovely Bill X, and I would remember that Sunday off when we got up at 6 A.M., rode to my home on our bikes, and there played tennis and browsed in the strawberry bed alternately till it was time to ride back. Was it 15 or 20 sets we played? And (no, it can't be: yes it is) that scraggy old bird next to him, with a collar four sizes too big, was once Peter Y. I remembered hearing he'd been ill. He was the one who ate so many cream horns that the Head said he was getting like one. He looked as if he could do with a few now—and a wash.

I managed to catch Norman in the cloakroom on the way out and fix up to meet him at Lyons Corner House, so I needn't go next year.

* * *

Last week's disclosure that medical discussions are to be broadcast in the United States, has given me a further idea. Instead of medical journals let us have medical recordings. Then the medical library of the future will have rows of those comfortable cubicles where you can try your choice, like the gramophone shops, with perhaps a few studios for films. It is so much easier to listen than to read. Except, of course, that you cannot skip the dull bits.

* * *

Topical Terminology

Pædiatrician to mother: Is there any tuberculosis in the family?

Mother: Oh, that's all right, doctor. He was patched last month.

Letters to the Editor

SOCIAL SIGNIFICANCE OF SYMPTOMS

SIR,—Dr. Gooddy's article in your issue of Feb. 11 is more than disturbing. It starts with some paragraphs of crypto-political exposition containing a number of assumptions which could hardly be argued out in your journal. The views put forward appear to lead to a somewhat derogatory attitude towards social security, the psychiatrists, and the individual about whom this article is most concerned. Is this latter, for example, the only person who smokes under the "no-smoking" notice? Is he any worse than the patient who walks into my consulting-room smoking without permission, equally idle, equally improvident of other people's resources, but who does think that I can help him?

It would appear that there are three classes of patients in Dr. Gooddy's mind—those with organic disease, those with some psychopathology, and, in between, a definable group whose troubles arise from social circumstances, and whose difficulties are therefore not in the province of medicine.

What is this group? Perhaps Dr. Gooddy's experience in Queen Square with its highly selected sick population is not common experience; and I certainly cannot identify this impatient, ill-behaved, certificate-seeking individual, who is supposed to blackmail me with his blackouts and gastritis and fibrositis, the sequel of conscription, change of job, or amatory setback (often precipitated by seeing a romantic cinema programme). If I could identify this patient who is unadjusted because of his social background from amongst all those whose symptoms are expressed with a lavish use of superlatives and exaggeration, I would have to include many people with organic disease and perhaps all my Irish patients, whose language is naturally a rich one. In the definition of this group the causes of the disability include constitutional defects, defective education and social opportunities, and particularly inadequate housing, susceptibility to medical advertisements, ignorance, and the desire to get something for nothing. Apart from the suggestion that the "something for nothing" may be a certificate to the housing authorities, I fail to see what this patient is after. Can it really be, perhaps, that he prefers to live on sick-pay instead of his normal wage, which is probably at least three times as large?

Finally, having stated that it is impossible for the medical profession to help such patients in these matters, a solution of the problem is suggested. This consists in replacing the doctor's scientific approach by an attempt to achieve a dogmatic statement in every case—to be able to tell the patient, after a thorough examination, that it is certain that there is nothing wrong with him and to offer him sympathy and the exit door of the outpatients' department. I cannot help remembering that most of my medical mistakes in missing grave organic disease have occurred in two groups of cases: firstly, those whose description of their symptoms has sounded exaggerated; and secondly, and most importantly, those who have had the most complete and repeated examinations.

When one remembers the attitude of the medical profession in the Victorian era towards the work of social reformers and public-health authorities, when one recalls the attitude of the Royal Colleges to the report on the fitness of Boer War recruits, one should be a little humble before defining the scope of the work of the doctor. If these patients come to see me seeking my help, I will think it within my province on that account alone. Medicine is a social function and the job of the doctor relates to the maintenance of health and care of sickness of the individual living in society. If *illness* arises from any maladjustment of the individual's relationships, then it is a province of medical study.

Lastly although medicine must have a basis in the study of "the common man," such sociological study will not be promoted by the mere assertion, in ex-cathedra statements, of the effect of the welfare State.

London, W.1. HUGH GAINSBOROUGH.

SIR,—I was greatly interested in Dr. Gooddy's article. Many points stimulate thought and I should like to take one or two for comment.

In the Services in the forward areas the psychiatrist was the man to whom the commanding officer and the medical officer "passed the buck." They knew the man was no good to them, and the easiest way to get rid of him was to get him removed from the unit or from the Service on psychiatric grounds. The psychiatrist pronounced the necessary incantation and absolved them of responsibility for throwing a man out. As Dr. Gooddy says, this is not possible in peace-time, though some attempt it. In the Army or out of it one is constantly coming across the remark "the psychiatrist said" delivered in a tone which brooks no argument. The witch-doctor has spoken; the patient has an alibi for his failure successfully to tackle the problems of life.

The problem of giving advice without a bottle of medicine is a difficult one, especially when livelihood depends upon keeping patients. In essence there is little difference between the African native who goes to his weirdly dressed witch-doctor and comes away with a snakeskin or other charm, and the patient who goes to his doctor's consulting-room and emerges triumphantly with a medicine bottle of value equivalent to coloured water. Advice is good, perhaps, but a bottle of medicine is something one can see and taste, a charm, and represents value for money in the eyes of the patient.

An important aspect, which Dr. Gooddy does not mention, is the social significance of doctors' certificates. I am engaged in industrial medicine and see large numbers of patients who return to work armed with doctors' certificates. A significant proportion of these people are of the type discussed in Dr. Gooddy's excellent paper, and I am impressed with the faith they have in the certificates and the way they use them to justify their absence and ailments.

I have spent quite a lot of time explaining to some of these people that certificates are in many cases no proof of illness and in that respect are not worth the paper they are written on. It is explained to them that the certificate is a sign of the doctor's acceptance of their word that they have a pain in the head or the back, which in their (the patients') opinion is sufficient to prevent work. It is a paper provided by the doctor to enable them to justify their absence to the employers, or to qualify for sick benefit. I do this not to undermine confidence in their doctor but to try and persuade them to face their mental and social problems. Sometimes I have apparent success. I appreciate the value of a bottle of medicine as a vehicle to facilitate the acceptance of good advice; but how often is this expediency justified?

Often I am glad that as an industrial physician I cannot prescribe drugs, because I am spared the temptation to take the easy way out, and that having a salary I can speak with that little extra freedom which fear of financial loss might constrain. The process of learning is endless, but I still think the advice of Lord Horder to the medical students of Westminster is most apt: "Un peu de savoir, assez de faire savoir, et beaucoup de savoir faire." In the breadth of medical practice few things seem more important than human understanding.

The practice of medicine is becoming an important political issue, and the social significance of symptoms requires deep thought.

Stoke Park, Slough, Bucks. M. E. M. HERFORD.

SIR,—Dr. Gooddy deserves praise for ably drawing attention to one of the major problems in medical practice, although one may disagree with his conclusions.

For the most part he has discussed the symptoms of a single syndrome, which is perhaps the commonest for which adults seek medical advice. It has many names—Da Costa's syndrome, anxiety state, nervous dyspepsia—and in our opinion it can be recognised by its own characteristic features, without endless special investigations to exclude other conditions, and can be successfully treated in general practice.

A general practitioner is economically dependent on the good will of his patients. The "altercations and scenes" which he risks by an honest approach are not the only cause of his reticence. He may lose the patient and his family and friends, and their capitation fees. Moreover, a practitioner with a full list seldom has the time to educate the patient to understand the cause of his trouble. Instead he gives a tonic or other placebo.

The customary attitude of "disbelief in any symptoms . . . not . . . primarily due to a disease process" is no solution, and is in part responsible for the patient's feeling of frustration and injustice. It is right, after arming oneself with the authority of a full history and physical examination, to explain to the patient that there is no organic disease causing his symptoms; but the next step is to explain dogmatically the relationship between his symptoms and his emotional state. Treatment is started by an inquiry into the social factors causing his emotional disturbance. This approach gains the patient's confidence because the doctor accepts and explains his symptoms instead of denying their existence. Contrary to Dr. Gooddy's advice, we must be prepared to take a positive attitude to the social problems responsible for our patients' illness.

The patient whose symptoms are not due to "structural disease or a psychopathological process" is a malingerer, and in our experience is seldom encountered and is easily dealt with.

It is true that we cannot make our patients all "clean, rich, educated at a public school"; even if we could do so, we could not promise immunity to this syndrome. But we can take part in the fight against such social evils as bad housing and schooling, economic insecurity, and preparations for a third world war. If we are not prepared to do so we must accept the medical problems which they create.

L. M. FRANKLIN
St. Paul's Cray, Kent. J. D. PAULETT.

THE FUTURE OF COMMUNITY CARE

SIR,—Your leading article of Feb. 4 was most encouraging to the workers of a voluntary body such as ours concerned with the community care of the mentally handicapped. These patients present a peculiar problem to the medical and lay public. There is still a great deal of fear and superstition attached to the idea of mental illness of the psychotic type. The minor mental maladies, the psychoneuroses, are looked upon by many with contempt, as indicating "poor moral fibre," and as not requiring skilled care and attention.

The alarm caused by the onset of an acute psychiatric condition results in the speedy removal of the sufferer to a mental hospital. That many people prefer to push the whole problem of the patient and his illness to the back of the mind is shown by the fact that some of the mentally handicapped under hospital care are rarely visited by their relatives. Indeed, many doctors betray a similar lack of understanding of mental illness, and a desire to avoid handling it and to shift the responsibility elsewhere. As long as acute mental ill health is looked upon as an unpredicted volcanic eruption for which nothing can be done beforehand, and which is due to genetic and constitutional causes not amenable to prophylactic measures, so long will mental health be little regarded in the health services.

True, predisposition plays a large part in the onset of these illnesses; but work in recent years has demonstrated that the factors precipitating breakdown can be minimised by a favourable environment.

A parallel can be found in the excellent work of the National Association for the Prevention of Tuberculosis. In the very early days "galloping consumption" was looked upon with fear and superstitious horror as the "white man's disease." The measures for prevention were little understood until Sir Robert Philip made the community tuberculosis-conscious. The aftercare and following up of these cases has since advanced greatly; and under the Factories Acts prophylactic hygienic measures pay good dividends, while mass miniature radiography is increasing the number of cases diagnosed early.

This is the sort of approach that we feel the mental-health services could adopt. Early detection of the strains and stresses provoking psychiatric breakdown is essential. The strains and stresses may be modified; or if that is not wise or possible, the attitude of the potential patient to them could be changed, and his resisting power increased by an understanding of his modes of reaction. Mental hygiene depends so much on knowledge, which gives insight, and hence power to behave differently.

This seems to me to be eminently the job of the medical officer of health. He has unlimited powers under section 28 of the National Health Service Act of 1946, which provides for community care of a preventive and educative kind, as well as for rehabilitation and resettlement after clinic or hospital treatment. The volume of demand for treatment of psychiatric conditions grows, and there never will be enough trained personnel to cope with therapy. We have to tackle the problem at the stage of early signs and symptoms and develop a preventive and prophylactic service which will diminish the stream of sufferers crowding the psychiatric units. These diseases form from a quarter to a third of all illnesses.

This association is arranging short courses on public mental health designed to interest those concerned with social medicine.

National Association for Mental Health. **ALFRED TORRIE**
Medical Director.

HIRSCHSPRUNG'S DISEASE

SIR,—In your issue of Jan. 7 Bodian, Stephens, and Ward published a second communication on the clinical and histological findings in Hirschsprung's disease. Their main contribution to the understanding of the clinical picture and pathology of this condition has been the demonstration of a distal narrow segment of the large intestine, which is characterised histologically by the absence of intramural ganglion cells, and the presence of abnormal nerve-bundles in the customary sites of the intramural plexuses.

In 1945 [1] we described a condition in the large bowel in cases of generalised scleroderma with histological changes identical with those found by Bodian and his co-workers in Hirschsprung's disease. Our cases showed narrowing of part of the transverse, descending, and sigmoid colon, the narrowed parts being hard and fibrous; and a number of sacculi were seen. Above and below, the colon became abruptly dilated and the wall was very thin and atrophic.

Histological examination of the narrowed portions was reported on as follows:

> "The most striking feature of a section through the narrowed part of the transverse colon is the size of the organ. It is barely larger than a normal, fair-sized, appendix. The lumen is almost completely occluded. . . . As can be seen even on such a small enlargement, the myenteric plexus is very prominent and is characterised by a conspicuous absence of ganglion cells. In many sections we find the whole plexus surrounded by a dense fibrous capsule."

In scleroderma, cardiospasm is a common complicating feature; and in the histological examination which we were able to carry out and described in the paper mentioned above, we found that the myenteric plexus becomes extremely prominent and in one patient formed "a proper neuromatous proliferation." This reminds one very much of the description given by Bodian and his co-workers for Hirschsprung's disease.

At the time we felt that the absence of ganglion cells and the fibrosis of the myenteric plexus suggested that "the motor activity of the bowel was interfered with by some intrinsic nervous disorder brought about by the involvement of the intramural neuro-muscular apparatus."

It is of interest that in two so apparently different conditions as Hirschsprung's disease and scleroderma narrowing of portions of the large bowel is found, and that in both instances these areas of the bowel prove to be characterised by an absence of ganglion cells from the intramural plexuses.

FILARIA AND LOEFFLER'S SYNDROME

SIR,—Dr. Malhotra's case-histories (Jan. 28) were significant as the association of bronchitis and eosinophilia with filariasis has not previously been described in India. This association has, however, been described in the West Indies [1] and in the East Indies.[2] One feature which distinguishes Dr. Malhotra's cases is the finding of microfilariæ in the blood. Cases in the West and East Indies were all negative in this respect, the diagnosis being made from lymph-gland biopsies.

I have been investigating cases of so-called tropical eosinophilia in Vellore, South India, and I could find no evidence that filariasis played any part in that region. Night-blood examined for microfilariæ by a concentration method [3] in 15 cases was negative. I found that 63 of a series of 100 cases had enlarged lymph-glands, and performed 7 biopsies where these were particularly prominent. Serial sections revealed no microfilariæ.

These cases of Dr. Malhotra's show that filariasis should be added to what seems to be a growing list of the pulmonary lesions which can cause eosinophilia. Apley and Grant [4] enumerate bronchial asthma, pulmonary amœbiasis, ascariasis, periarteritis nodosa, Loeffler's syndrome, tropical eosinophilia, fascioliasis, and possibly acariasis. Willett and Oppenheim [5] add to these trichinosis, pulmonary brucellosis, ancylostomiasis, strongyloidiasis, and, from their own experience, pulmonary coccidiomycosis. Even this is not complete as one must add pulmonary schistosomiasis.[6] Though pulmonary infiltration and eosinophilia can occur in both sarcoidosis [7] and Hodgkin's disease, they do not appear to be associated in the same patients.

FLATULENCE IN INFANCY

SIR,—I read with interest Dr. Tanner's letter of Feb. 4. Extension of the infant's neck while swallowing seems to be a vital factor in avoiding flatulence. For some years now I have advised mothers to hold their baby upright when feeding from either the breast or bottle. When breast-feeding, the mother can relax against pillows or chair-back and hold the baby's body upright in a very comfortable position for both. The baby does not swallow so much air, and the mother's back is rested instead of being strained as it is in the forward position usually adopted.

When the baby has to be "walked" at night, I suggest that he is held in a vertical position over the shoulder of the walker. Wind comes up easily, and the baby can drop off to sleep again with his head on the napkin previously placed to protect the male dressing-gown shoulder!

London, E.11. MARY BELTON.

DECAMETHONIUM IODIDE

SIR,—Dr. Gray's article in your issue of Feb. 11 calls for comment.

The use of any of the group of muscle-paralysing drugs in anæsthesia implies diminution of respiratory movement. It has been claimed for each new drug of this class that respiratory depression is minimal; but it follows that any drug which produces relaxation of the abdominal muscles by blocking motor impulses must inevitably have the same action on the muscles of respiration. Decamethonium iodide, used in dosage to produce adequate abdominal relaxation for surgery, causes diminution of respiratory movement in all cases and complete cessation of respiration in most. This is, however, no disadvantage, since it enables the technique of controlled respiration to be performed with ease.

Dr. Gray states that "assisted respiration" was necessary for the first few minutes in his cases. The performance of assisted respiration for a patient who retains some respiratory movement is most difficult and depends on the exact synchronisation of the inspiratory impulse with the patient's own inspiratory effort. If synchronisation is not perfect, the respiratory exchange will be even poorer than if no assistance were given. Controlled respiration, on the other hand, is without the complication of the patient's own respiratory effort.

The "element of insufflation" which Dr. Gray introduces, by means of screwing down the expiratory valve of the anæsthetic machine, would seem to me to be useless without full movement of the chest and therefore full respiratory exchange.

Neither assisted nor controlled respiration should be employed without ensuring some means of carbon-dioxide excretion. In the present state of our knowledge, this can only be done by means of carbon-dioxide absorption. The management of nitrous oxide and oxygen anæsthesia in a closed circuit presents problems, because of the difficulty of maintaining a steady percentage of oxygen; but this can be accomplished by leaving the expiratory valve slightly open and by using a greater volume of anæsthetic gases.

Failure to ensure an adequate respiratory exchange or to use carbon-dioxide absorption may lead to delayed recovery in one of two ways: firstly, it will lead to suboxygenation, which will give rise to relative cerebral anoxia; secondly, an increase in alveolar carbon dioxide will result in a raising of the threshold of stimulation of the respiratory centre, which, in turn, will lead to prolonged apnœa when the anæsthetic is discontinued and alveolar carbon dioxide is blown off.

As to the case reported by Dr. Gray, that of a stout woman who was kept in the Trendelenburg position presumably for the greater part of the duration of the operation (1 hr 25 min.), it is obvious that to produce an adequate respiratory exchange is no easy matter, whatever the anæsthetic used; adequate controlled respiration undoubtedly offers the best means. At the end of the operation, says Dr. Gray, the respiration was "slow, shallow, and jerky, being chiefly intercostal rather than diaphragmatic." This is not the picture of respiratory paralysis caused by the muscle-paralysing drugs, nor, indeed, of that produced by the deeper planes of anæsthesia with the ordinary inhalational agents, where the sequence of events is always that the intercostal muscles are paralysed before the diaphragm and function returns to the diaphragm before the intercostal muscles. The further progress of this patient can be ascribed, as I am sure Dr. Gray would agree, to the use of pentamethonium iodide.

Dr. Gray has discarded decamethonium iodide because of this case and others of a similar nature, all of which, presumably, had reacted favourably to the test dose used; also he considers that no satisfactory antidote exists. He has reverted to the use of *d*-tubocurarine chloride. It is, I think, as well to remember that neostigmine is not a direct pharmacological antidote to *d*-tubocurarine chloride and that the only real antidote to muscular respiratory paralysis is artificial respiration.

I have used decamethonium iodide routinely in a comparable series of abdominal cases, taking care to ensure adequate respiratory exchange, and have not encountered the phenomena described by Dr. Gray. I feel that it is a most useful drug which, owing to its rapid and complete excretion, has many advantages over *d*-tubocurarine chloride, particularly in the shorter surgical procedures.

Pinner, Middlesex. T. B. L. ROBERTS.

AUREOMYCIN IN STEVENS-JOHNSON SYNDROME

SIR,—Having read Dr. Church's account (Feb. 11, p. 281) of a case of Stevens-Johnson syndrome treated with 'Aureomycin,' I would like to record the following case where the response to treatment was equally dramatic.

A man, aged 21 years, was admitted to this hospital on Jan. 6, under the care of Dr. Ivan H. McCaw. On admission he was suffering from severe acute stomatitis with submucosal bleeding ulcers of the entire mouth and gums, and extending to the throat and nasopharynx. He was unable to swallow or speak properly, was in great pain, and for several days had been without food. Associated with this was mild conjunctivitis and urethritis, both of which the patient stated had been more severe before admission. On the limbs only there were several bullous erythematous lesions. The temperature was 100°F. The appearances were typical of Stevens-Johnson syndrome.

On examination no abnormality was noted in the cardiovascular, respiratory, gastro-intestinal, or central nervous systems. The blood-pressure was 120/75 mm. Hg. Dark-ground illumination of a smear from the mouth was negative for Vincent's organisms. The urine contained no albumin, and culture was sterile; microscopic examination of a urethral smear showed pus and epithelial cells. Examination of peripheral blood and blood-culture revealed no abnormality.

Before admission to hospital the patient had received six injections of penicillin, and on admission he was given penicillin 500,000 units daily, ascorbic acid 100 mg. thrice daily, and antiseptic mouthwashes. This treatment was continued for three days with no improvement, the temperature remaining 100°F and the mucosal lesions continuing to cause severe distress.

On Jan. 9 aureomycin—1 g. 6-hourly—was commenced. Within twelve hours the temperature became normal and it remained so. The following day the mouth showed definite clinical improvement; and two days later, since he was now quite well, aureomycin therapy was discontinued. On Jan. 16 the patient was discharged.

Royal Victoria Hospital,
Belfast. MARGARET A. LYNAS.

TUBERCULOSIS

SIR,—The recent correspondence in the *Times* has focused attention on undergraduate education in tuberculosis. To many engaged in the specialty this has long been a matter of serious concern. It has been pointed out, for instance, that the average time elapsing between a patient consulting his doctor and reference to a chest clinic is over three months.[1] Only too often the patient himself makes the diagnosis after medical advice has failed to satisfy him.

It is not suggested that the standard of undergraduate teaching is solely responsible for this failure to appreciate significant clinical facts. Clearly, however, the time has come for every teaching hospital to re-examine its programme of instruction in tuberculosis in the light of present realities. Even those hospitals which already have special provision in this respect should ask themselves if more can be done. Tuberculosis is still taking a tremendous toll of lives (over 400 a week in England and Wales alone) and workers in this field are in sore need of help in a form which the teaching hospitals alone can provide—namely, the well-equipped graduate who knows the basic facts about tuberculosis and can apply them, whatever field of medical work he may enter.

It is unfortunately true that too many students reach the stage of qualification with a sketchy and functionally inept knowledge of the subject. Moreover, they have the impression that this is a matter of little consequence; that tuberculosis is manifestly dull and uninteresting; and that for the most part it will be of little importance to them in the future. That keen young minds should consistently arrive at conclusions so much at variance with fact is little short of tragic. Where, indeed, is the balance we are given to understand exists in the system of teaching? Nurses, not unnaturally, derive from their training an impression of tuberculosis similar to that of young medical graduates, and this warping influence is an obvious handicap to recruitment in chest hospitals and sanatoria.

The blight extends much further. Regional boards are frequently guilty of according tuberculosis the lowest priority in spite of abundant evidence of need; and any legislative action is undertaken tardily, grudgingly, and with no pulse of urgency behind it.

The effect of reorientation of outlook at the teaching level would be of incalculable benefit—its revitalising influence would be felt immediately in every quarter. Students should learn not only the essential clinical, social, and preventive aspects of tuberculosis but also how to use the organisation for dealing with it; and they should be given a balanced appreciation of the significance of the disease in relation to other causes of illness. This correction of perspective can only come about if every teaching hospital possesses its own tuberculosis unit and if the students are taught in the chest clinic as well as at the bedside. Much more use could also be made of the opportunities afforded by tuberculosis in its many organic forms for integrating knowledge of separate systems; and study of the disease also enables the complementary claims of clinical and environmental medicine to be placed in their proper relationship.

Tuberculosis offers a variety of interest and challenge that will more than satisfy the most lively intelligence. It is no longer a single or isolated specialty but requires the integrated efforts of physician, surgeon, anæsthetist, radiologist, pathologist, biochemist, laboratory research-worker, statistician, sociologist, and many others. The sustained inflow of keen, intelligent, and interested minds into all these professional channels is another vital necessity.

The World Health Organisation has accorded tuberculosis major priority in its list of problems demanding immediate urgent action. While it is true that certain commendable steps have been taken in teaching hospitals to improve the standard of education in this subject, can it really be that in the present grim emergency nothing more can be done?

Claro Hall Hospital,
South Mimms.

NORMAN MACDONALD.

---

[1] Stradling, P. *Brit. med. J.* 1948, ii, 832.

SIR,—I regret that I may have conveyed a false impression by including a particular example of the tuberculosis bed situation in my letter last week.

The board of governors to whom I referred have extensive medical educational commitments which already impose a severe strain on their accommodation. The medical school concerned took the forward step some years ago of accommodating the borough tuberculosis dispensary in order to ensure the availability of a clinic for postgraduate teaching in tuberculosis. Beds available to them in other hospitals at that time have been lost through the rearrangement of hospitals since the appointed day. Active negotiations are now being undertaken to correct the deficiency by arrangement with the regional board. I deeply regret any embarrassment to the authorities concerned which may have been caused by my letter.

Hammersmith Chest Clinic,
Hammersmith Hospital,
London, W.12.

PETER STRADLING
Chest Physician.

KIDNEY EXPOSURE THROUGH THE TWELTH RIB

SIR,—Mr. Sames is to be thanked for calling attention last week to the use of an incision through the bed of the twelfth rib for exposure of the kidney. I can corroborate all that he says about the advantages of this exposure, which I have used, almost continuously, for twenty years. No other incision gives as good an exposure of the renal pedicle; and I have, for this reason, found it particularly useful when denervating the kidney.

The only disadvantage of this incision is the risk of opening the pleura. The pleura comes down to the twelfth rib only over its inner part, as Mr. Sames shows in fig. 2 of his paper; and for this reason the periosteum of the rib bed should be incised at its outer part, for then there is no risk of injury to the pleura. The incision can then be carried backwards by gently separating the fibres with the fingers. In this way the pleura is pushed to one side and the risk of injuring it is minimised.

Liverpool.

J. B. OLDHAM.

SIR,—As one grows older, one appreciates the saying that there is no new thing under the sun. Just as Hey Groves had devised and practised the radical operation for cancer of the stomach in 1910,[1] so Deanesly, of Wolverhampton, was approaching the kidney through the bed of the twelfth rib for ten years before he published the method in 1911.[2]

Northampton.

C. C. HOLMAN.

SIR,—The benefit of the incision advocated by Mr. Sames for exposing the kidney was brought home to me sixteen years ago, when I first used it in performing an adrenalectomy. I have used it on occasion since, though not as a routine. The removal of the last rib, by extending the field, reduces the depth at which one appears to be working, at the same time affording protection to important structures such as the pleura and 11th and 12th dorsal nerves. My small experience supports Mr. Sames in his contention that the advantages of this approach as compared with the *classical* are such that it deserves wider recognition.

St. Andrew's Hospital,
London, E.3.

J. R. M. WHIGHAM.

THE FORGOTTEN SWAB

SIR,—In connection with your excellent leading article last week, I am writing to ask if you know of any hospitals in this country that are fortunate enough to be able to obtain a type of swab, manufactured in the U.S.A., that has a fine metal thread incorporated in the material. We managed to obtain samples of these swabs from Illinois and New Jersey, and have tried them in the pathological department, where they have been found to be satisfactorily visible with X rays. I have made many inquiries among manufacturers in this country, and am told that the supplies of gauze do not warrant the production of these swabs in this country. We have approached the Ministry of Health and have been told that they anticipate difficulty in getting any firm to adopt the manufacture, as it would not be an economical proposition for the weavers.

If these swabs could be obtained they would be an additional protection for the patient, but they would not of course exonerate the theatre team from taking the usual careful precautions enumerated in your article.

It seems a very great pity that the manufacturers in this country cannot divert some of the existing gauze already made into theatre swabs to make the particular type described above. It is quite obvious that by making these, the number of swabs and the amount of cotton gauze would in no way be increased. This problem is of such vital importance to the patient and also to the surgeons and the theatre staffs that I would be most grateful for any help you could give us.

The London Hospital, E.1.
CLARE ALEXANDER
Matron.

TREATMENT OF WOUNDED IN MALAYA

SIR,—Dr. Binning, in his letter which appeared in your issue of Dec. 31, expressed concern lest the lessons of medical tactics learnt in the war of 1939–45 might be in danger of being forgotten. In particular he feared that early surgical treatment was not being afforded to those who were wounded in the operations against the bandits in Malaya.

I should like to reassure Dr. Binning that the valuable medical lessons of the last war are not forgotten, and the experience gained in the campaigns in Burma forms the basis on which our present medical tactical doctrine in Malaya is founded.

The War Office, London, S.W.1.
N. CANTLIE
Director-General Army
Medical Services.

RUPTURE OF EXTENSOR TENDONS OF THE KNEE

SIR,—It is interesting to observe how frequently the principles of mechanics are ill understood or wrongly applied in medical literature. One recent example is in the explanation proffered by Mr. Fowler and Mr. Mitchell (Feb. 4) of the forces underlying rupture of the extensor tendon of the knee-joint.

They reproduce the old story that the factor which alters the mechanical disadvantage of the extensor tendon is a shifting fulcrum on the patella. But by far the most important factor, as I have shown,[1] is the distance of the patellar tendon from the axis of rotation of the knee-joint. In addition, they make the curious claim that the distribution of the forces is reversed according as the tibia or the femur is free to move. They deduce that when the foot is off the ground the force of the quadriceps acts to much better advantage in the extended than in the flexed position of the knee, but that if the tibia is fixed the reverse is the case. This is the sort of argument that has been advanced in many reports on the action of muscles, and it is at variance with the principles of mechanics. In actual fact the mechanical disadvantage of the quadriceps action on the knee is less in the extended than in the flexed position, irrespective of whether or not the tibia is fixed or movable; and the reason is that the patella in the extended knee is riding on the anterior surface of the femur and is holding the patellar tendon further from the axis of rotation.

As regards the cases to which Fowler and Mitchell refer, it does not appear justifiable to go further than to say that the whole extensor apparatus was subject to a sudden strain and rupture took place at the weakest point in each case.

Rationalisation is a good thing in so far as it clarifies and aids understanding, but it must be accurate and should not be taken too far.

Manchester.
H. A. HAXTON.

SERUM-AMYLASE

SIR,—The annotation on the significance of raised serum-amylase readings in your issue of Feb. 11, conveys the impression that Musgrove,[1] of the Mayo Clinic, is the first to describe its occurrence in free perforations of gastroduodenal lesions. I should like to point out that Hughes [2] read a paper on this interesting side-effect to the Royal Society of Medicine in 1942, the only difference in his approach being in the use of the urine as the medium of study. My own paper on the serum-amylase and serum-lipase changes in a series of 30 cases of perforated peptic ulcer was published in this journal last year.[3] To Musgrove, however, must go the credit for the supposition that the alterations in the blood-levels are due to absorption of the pancreatico-duodenal juices lying free in the peritoneal cavity. In the other reference in your annotation, Pemberton, Grindlay, and Bollman,[4] also of the Mayo Clinic, are quoted as having confirmed the absorptive theory by experiments carried out on dogs.

I subscribed to the view that peritonitis leading to some derangement of pancreatic function might be the explanation; and it is to be noted that the three cases with abnormal amylase values cited by Musgrove had generalised peritonitis. It so happens, however, that I too gave serious consideration to, and carried out some experiments to substantiate, the absorptive theory. Whether or not it was due to the existence of incalculable variables one cannot say, but the results turned out to be meaningless and were therefore discarded. Moreover, I considered that the inclusion of doubtful data would only detract from the point of my article, which was in the nature of a warning to surgeons who are apt to place too much reliance on a biochemical diagnosis. Now that this problem is beginning to arouse some attention, this work may be worth publishing even if only to show how difficult is the clinical approach to it. This I hope to do in the near future.

Western Infirmary, Glasgow.
HENRY WAPSHAW.

SIR,—We were most interested in your annotation of Feb. 11, and felt that the following case was of interest in this connection:

A man, aged 32, was admitted to this hospital, under the care of Mr. J. H. Conyers, on Feb. 12, 1949, with violent epigastric pain of $1^{1}/_{2}$ hours' duration. The pain was constant, went through to the back, and made him sit up and lean forward to obtain partial relief. One hour after the onset of the pain he began to vomit repeatedly; the vomitus consisted of clear fluid and a little sediment. For a few weeks before admission he had had a constant ache in the right iliac fossa.

On examination he was in obvious pain and slightly shocked. He vomited every few minutes and sat upright with the hands

---

1. Musgrove, J. E. *Proc. Mayo Clin.* 1950, 25, 8.
2. Hughes, E. B. *Proc. R. Soc. Med.* 1942, 35, 339.
3. Pemberton, A. H., Grindlay, J. H., Bollman, J. L. *Proc. Mayo Clin.* 1950, 25, 5.
4. Wapshaw, H. *Lancet*, 1949, ii, 414.

clasped across the abdomen. Movement appeared to cause no pain and there was no sign of jaundice. The blood-pressure was 134/64 mm. Hg, the pulse-rate 60 per min., and the temperature 97°F. The abdomen moved well but there was tenderness over the whole of the upper abdomen; peristaltic sounds were absent. X-ray examination of the abdomen showed no evidence of free gas in the peritoneal cavity.

A diagnosis of acute pancreatitis was made, and this was strengthened by the finding, eight hours after the onset of the pain, of a urinary diastatic index of over 200 units. This test was carried out with fresh solution and adequate controls.

Conservative treatment was instituted and carried on until Feb. 17, when recurrence of vomiting with a rising pulse-rate and abdominal distension led to the decision to perform laparotomy. Free fluid was present in the abdominal cavity, and 2 ft. of the terminal ileum were found to be the site of regional ileitis. Resection of the affected gut was carried out and the patient made a good recovery. Histological examination of the excised intestine confirmed the diagnosis of Crohn's disease.

It is interesting to speculate on the cause of the high urinary diastatic index in this case. It is known that after total removal of the pancreas, the blood and urine amylase levels soon return to normal and that most of the dietary carbohydrate can be digested in such circumstances.[1] We feel that it is possible that the cells of the ileum may contain amylase, which is liberated as a result of the hyperæmia due to inflammatory lesions, and thus cause elevation of blood and urine diastase levels in cases such as the one we have described. We should be interested to know if any of your readers have had a similar experience with inflammatory conditions of the small intestine.

We wish to thank Mr. J. H. Conyers for permission to report this case.

THE WRONG DRUG

SIR,—In the letter of Feb. 11 from Dr. Cid dos Santos, which records death following instillation of a solution of cocaine into the urethra, no mention is made of possible methods of treatment. In an accident of this sort it would, I think, be worth trying the intravenous exhibition of a soluble barbiturate to control convulsions caused by the local anæsthetic.

London, W.1. HUGH DUNLOP.

EFFECT OF DEOXYCORTONE ACETATE AND ASCORBIC ACID ON CIRCULATING EOSINOPHILS AND LYMPHOCYTES

SIR,—In view of the recent correspondence on the use of the above drugs in rheumatoid arthritis, we investigated the changes in peripheral eosinophils and lymphocytes in four patients in the fasting state over periods of $5^1/_2$ hours; two patients were suffering from rheumatoid arthritis, and two had a peripheral eosinophilia.

Peripheral-blood examinations were made following the injection of deoxycortone acetate and ascorbic acid in the dosage recommended by Lewin and Wassén[2]; and as a control, these were repeated a few days later under fasting conditions over a similar $5^1/_2$-hour period not preceded by any injection. In no case did the drugs have a significant effect on the peripheral eosinophil or lymphocyte level. These findings would seem to be consistent with Le Vay and Loxton's[3] view that these drugs act, not through the production of 'Cortisone,' but by a peripheral mechanism.

E. K. BLACKBURN
J. B. BURKE.
Sheffield.

THE CHEST PHYSICIAN

SIR,—Chest physicians throughout the country share the concern expressed by Dr. Toussaint in your issue of Feb. 11. The Ministry's attitude was made clear at a meeting of treasurers of regional hospital boards held at the Ministry of Health on Nov. 2, 1949. Boards were advised that

> "the proper course to adopt was for the Tb. Officers to have separate part-time contracts: (*a*) with the Regional Hospital Board, and (*b*) with the Local Authority. For this purpose, where the two part-time contracts together were intended to amount to full-time employment it was necessary for the Regional Hospital Board and the Local Authority to agree as to the proportion of the services of the Officer which each employing body required. As Regional Hospital Boards had no power to employ staff to carry out L.H.A. duties, it was not a proper arrangement for the Regional Hospital Board to enter into a full-time contract with the Officer under which he would be paid by the Regional Hospital Board the full-time salary at the rate specified in document enclosed with R.H.B. (49) 85 and for the Local Authority to pay to the Regional Hospital Board an amount for the time given by the Officer to the Local Authority service *calculated at the lower rate of salary at present payable by the Local Authorities to such Officers.* If the combined duties of the Tuberculosis Officer add up to full-time employment, the Officer was not entitled to the weighting factor applicable to part-time employment. The weighting factor would only apply where the combined duties amounted to part-time employment only."

The following resolutions have been accepted by the tuberculosis group committee of the British Medical Association and by the Central Consultants' and Specialists' Committee:

1. That a practitioner engaged predominantly in work for a regional hospital board and also giving part of his time to work for a local authority should be employed under one contract by the authority in whose duties he is predominantly engaged. The authority for which the smaller proportion of work is done should reimburse the employing authority and not the individual officer. Where the rate of repayment is higher than that received by the officer under his employing authority, a corresponding addition should be made to his salary.
2. That work carried out by a chest physician on behalf of a local authority is consultant and advisory in character and is indivisible from his clinical work. The physician is able to do this work only by virtue of his skill and experience. Such work should be remunerated at a rate not less than the physician's appropriate rate according to the terms and conditions of service of hospital medical staff.
3. That practitioners in the specialty of chest disease should have the same freedom of choice between full-time and part-time employment as practitioners in other specialties, and that all superannuation rights should be safeguarded where a practitioner excercises the choice to transfer from full-time to part-time duties.
4. That it is contrary to the terms of service for a regional board to offer a whole-time contract for part-time duties, and that the terms of service do not give the regional board power to stipulate or determine the manner in which a part-time officer shall spend that part of his time not governed by his contract with the board.

It is clear that the employment of chest physicians is governed by the terms and conditions for hospital medical and dental staff and that the Ministry cannot legally depart from those terms and conditions except by prior mutual agreement or through the operation of Whitley machinery. Whether "Tb. Officers" still exist, or what are their conditions of service I do not know. Regional hospital boards must obey the Ministry's orders and will offer dual contracts. I suggest that chest physicians should regard the above resolutions as the only basis for negotiation.

Two points in Dr. Toussaint's letter call for further comment. My legal adviser tells me that the interim contracts now being offered, though unstamped, unwitclasped across the abdomen. Movement appeared to cause no pain and there was no sign of jaundice. The blood-pressure was 134/64 mm. Hg, the pulse-rate 60 per min., and the temperature 97°F. The abdomen moved well but there was tenderness over the whole of the upper abdomen; peristaltic sounds were absent. X-ray examination of the abdomen showed no evidence of free gas in the peritoneal cavity.

A diagnosis of acute pancreatitis was made, and this was strengthened by the finding, eight hours after the onset of the pain, of a urinary diastatic index of over 200 units. This test was carried out with fresh solution and adequate controls.

Conservative treatment was instituted and carried on until Feb. 17, when recurrence of vomiting with a rising pulse-rate and abdominal distension led to the decision to perform laparotomy. Free fluid was present in the abdominal cavity, and 2 ft. of the terminal ileum were found to be the site of regional ileitis. Resection of the affected gut was carried out and the patient made a good recovery. Histological examination of the excised intestine confirmed the diagnosis of Crohn's disease.

It is interesting to speculate on the cause of the high urinary diastatic index in this case. It is known that after total removal of the pancreas, the blood and urine amylase levels soon return to normal and that most of the dietary carbohydrate can be digested in such circumstances.[1] We feel that it is possible that the cells of the ileum may contain amylase, which is liberated as a result of the hyperæmia due to inflammatory lesions, and thus cause elevation of blood and urine diastase levels in cases such as the one we have described. We should be interested to know if any of your readers have had a similar experience with inflammatory conditions of the small intestine.

THE CHEST PHYSICIAN

SIR,—Chest physicians throughout the country share the concern expressed by Dr. Toussaint in your issue of Feb. 11. The Ministry's attitude was made clear at a meeting of treasurers of regional hospital boards held at the Ministry of Health on Nov. 2, 1949. Boards were advised that

> "the proper course to adopt was for the Tb. Officers to have separate part-time contracts: (*a*) with the Regional Hospital Board, and (*b*) with the Local Authority. For this purpose, where the two part-time contracts together were intended to amount to full-time employment it was necessary for the Regional Hospital Board and the Local Authority to agree as to the proportion of the services of the Officer which each employing body required. As Regional Hospital Boards had no power to employ staff to carry out L.H.A. duties, it was not a proper arrangement for the Regional Hospital Board to enter into a full-time contract with the Officer under which he would be paid by the Regional Hospital Board the full-time salary at the rate specified in document enclosed with R.H.B. (49) 85 and for the Local Authority to pay to the Regional Hospital Board an amount for the time given by the Officer to the Local Authority service *calculated at the lower rate of salary at present payable by the Local Authorities to such Officers.* If the combined duties of the Tuberculosis Officer add up to full-time employment, the Officer was not entitled to the weighting factor applicable to part-time employment. The weighting factor would only apply where the combined duties amounted to part-time employment only."

The following resolutions have been accepted by the tuberculosis group committee of the British Medical Association and by the Central Consultants' and Specialists' Committee:

> 1. That a practitioner engaged predominantly in work for a regional hospital board and also giving part of his time to work for a local authority should be employed under one contract by the authority in whose duties he is predominantly engaged. The authority for which the smaller proportion of work is done should reimburse the employing authority and not the individual officer. Where the rate of repayment is higher than that received by the officer under his employing authority, a corresponding addition should be made to his salary.
>
> 2. That work carried out by a chest physician on behalf of a local authority is consultant and advisory in character and is indivisible from his clinical work. The physician is able to do this work only by virtue of his skill and experience. Such work should be remunerated at a rate not less than the physician's appropriate rate according to the terms and conditions of service of hospital medical staff.
>
> 3. That practitioners in the specialty of chest disease should have the same freedom of choice between full-time and part-time employment as practitioners in other specialties and that all superannuation rights should be safeguarded where a practitioner excercises the choice to transfer from full-time to part-time duties.
>
> 4. That it is contrary to the terms of service for a regional board to offer a whole-time contract for part-time duties, and that the terms of service do not give the regional board power to stipulate or determine the manner in which a part-time officer shall spend that part of his time not governed by his contract with the board.

It is clear that the employment of chest physicians is governed by the terms and conditions for hospital medical and dental staff and that the Ministry cannot legally depart from those terms and conditions except by prior mutual agreement or through the operation of Whitley machinery. Whether "Tb. Officers" still exist, or what are their conditions of service I do not know. Regional hospital boards must obey the Ministry's orders and will offer dual contracts. I suggest that chest physicians should regard the above resolutions as the only basis for negotiation.

Two points in Dr. Toussaint's letter call for further comment. My legal adviser tells me that the interim contracts now being offered, though unstamped, unwitnessed, and without date of expiry, are legally valid. Secondly, I think Dr. Toussaint does the local authorities an injustice in assuming that they have pulled the Ministerial strings. I have most reliable information that local authorities, together with the official organisations of medical officers of health, favour a single contract in the terms of resolution (1) above. In its proposals to the Joint Tuberculosis Council in 1946, the Ministry made clear its determination that the prevention of tuberculosis should be divorced from its clinical handling, and I drew attention to this in my letter to the *Times* of April 11, 1946.

Leeds Chest Clinic,
Leeds, 1.

FRANK RIDEHALGH
Consultant Chest Physician.

SIR,—Although I cannot be acquitted of having a personal, though small, axe to grind, I am not interested primarily in the subject of chest physicians' emoluments. Yet I believe that your annotation last week is sound sense and good doctrine, and will be acclaimed by chest physicians everywhere.

What I wish briefly to point out here—a consideration omitted from your annotation—is that by no means all of a chest physician's duties under section 28 of the N.H.S. Act are administrative and therefore worthy, presumptively, of an administrator's hire. As a minor illustration, two children with adult-type pulmonary tuberculosis were discovered recently in a large secondary school, having been referred originally to the chest clinic for diagnosis by their family doctors. The physician is now faced with the duty of visiting that school twice or oftener, and (*a*) tuberculin-testing, (*b*) clinically examining, (*c*) and X-raying and interpreting the chest films of, 50–60 adolescents (their parents having consented) and as many teachers as will volunteer for examination. Is that administrative work? And yet does it not fall to the chest physician's lot under section 28 (prevention, care, and aftercare)? You assert that "the Act leaves the responsibility for organising and conducting this section of the service with the local health authority." But, as in the above and similar instances, will the "conducting" not be, in practice, the responsibility of the chest-clinic staff?

Non-pulmonary tubercle continues to be notified, and cases of it referred to us. On receipt or intimation of notifications, the chest physician has an obligation to see those patients at his clinic or (if they are unable to attend) to visit them in their own homes, as, so far as I am aware, the old regulations covering his duties in this respect have not been rescinded or replaced by anything that is in the N.H.S. Act. Here, patients are still being referred to the chest clinic for diagnosis of swollen glands, abdomens, and joints, chronic diarrhœa, skin conditions, and chest-wall abscesses. I assume that when we take the necessary action on receipt of a non-pulmonary notification from the M.O.H.'s department, we are doing so under section 28—"care." These duties involve clinical decisions, confirmation, and sometimes reversal of the notified opinion, assessment of the case, and finally its disposal for purposes of treatment. Follow-up supervision of non-pulmonary cases must continue to be carried out for 3 years following quiescence of the disease. Such supervision is mainly clinical, and if we now stop this medical "care" work I do not know who will undertake the responsibility, or for how long.

Many other aspects of work and duties implicit in section 28 and coming under the heading "prevention, care, and aftercare," will fall to be done by former tuberculosis officers. Some of that work is non-administrative and can only be carried out by doctors, who have experience in tuberculosis. I would mention only two—rehabilitation and medical supervision of workers in Remploy factories, and B.C.G. vaccination.

I concur with the sentiments of your anonymous correspondent last week (p. 327). The bias of the health service is heavily on the side of treatment. In tuberculosis and other chronic diseases, "patching up" would often be a more accurate expression. If specialist advice and action on prevention is to be available, and if the chest physician is to leave his office and sanatorium or hospital ward and sally into the field, not only with his A.P. apparatus but with mobile X-ray unit and tuberculin, then he should be rewarded for this side of his work no less than for the clinical.

It used to be said, and wisely, that a tuberculosis officer's main job was not to treat tuberculosis but to prevent it. Sickness costs the nation 7% of its total annual income, but the prevention of disease is only $4^1/_2$% of the cost of sickness. I would wager that, in 1939–45, the nation expended more on the prevention of malaria, seasickness, and mustard-gas burns among her Armed Forces and population than the total expenditure incurred in tuberculosis prevention since 1921 when the tuberculosis service was set up. The salaries of those engaged in it will only form a small part of the total costs of prevention.

In the past, we have paid too often mere lip-service to prevention of tuberculosis. Let us see to it that we do not risk, by cheese-paring methods, a continuation of the same attitude towards the prevention of a disease that is the most clamant public-health problem of modern times in this country.

Tuberculosis Dispensary,
100, Coltman Street, Hull.

R. HARDY.

DIPHTHERIA IMMUNISATION

SIR,—There is much to be said for Dr. Bousfield's views (Feb. 11, p. 279) on the usefulness of the Schick test, and I think that our differences in the matter can be explained by one sentence in his letter: "in such an investigation as they have just described, blood-antitoxin titrations are essential if the fundamental facts are to be understood."

The Schick test is the only tool at our disposal for any large-scale investigation of the state of immunity of the population, whether the purpose be to obtain general information or to judge the efficiency of immunisation procedures. The conclusions to be drawn from the results are, however, very limited, and it is therefore highly desirable to obtain more detailed information by means of tests on blood-samples from small groups. Unless this is done, the fundamental facts are not really known and some wrong impressions may be registered. From the results of titration of blood-samples, a scheme can be drawn up as to how soon after immunisation routine Schick-testing would give information of value.

Dr. Bousfield believes that the Schick-negative state several months after inoculation can be accepted as the criterion of satisfactory basal immunity. This may be so, although in my experience a person giving a low-grade intermediate response may possess an antitoxic titre of 0·004 unit per ml. as long as nine months after the last injection of prophylactic. However, is satisfactory basal immunity all that is required at the present time? Some years ago, when the population received "natural boosting doses" from subclinical infections, good basal immunity probably was all that was necessary; but we cannot be sure that this is so today, when the incidence of diphtheria has become negligible and natural boosting doses almost non-existent. In a well-immunised population before the decline in the disease, the bulk of antitoxic values were very probably distributed around 0·2 unit per ml. and remained fairly steady, so that the great majority of Schick-negative subjects had titres far above the Schick level. In some work on young adults in which I am now collaborating with Dr. A. C. Cunliffe, and which we hope to publish very shortly, there are indications that this state of affairs does not prevail today. For this reason, not only sound basal immunity but antitoxic values far above the Schick level must be aimed at in the immunisation of young children, if the need for numerous boosting doses is to be avoided.

Any conclusions about the suitability of the Schick-negative state as a criterion for safety against clinical diphtheria can only have been drawn in the past, when there were epidemics; then the antitoxic values of the population were receiving intermittent boosts and were actually considerably above the Schick level. The fate, on exposure to infection, of people with antitoxic values only just above the Schick level is not known; but the high incidence of diphtheria among adults in epidemics in the occupied countries during the war, suggests that their antitoxic values had fallen in the absence of recent natural stimulation, and consequently they were inadequately protected by the basal immunity conferred by immunisation in childhood. It should be our aim to act on this experience, and attempt to immunise young children in such a way that reasonably good antitoxic titres are maintained into adult life.

Dr. Bousfield has done much valuable work with the aid of the Schick test, but I am convinced that a higher standard than the Schick-negative state is now required.

Finally, I hope that Dr. Bousfield was referring to boosting doses when he mentioned single-injection prophylaxis. Both the antitoxic response and the duration of antitoxic immunity increase with the number of injections given, and in these days when "natural boosts" are almost negligible, these factors are of the utmost importance.

The Wellcome Physiological Research
Laboratories, Langley Court,
Beckenham, Kent.

MOLLIE BARR.

ON WASHING THE DISHES

SIR,—Your timely annotation last week is of considerable interest not only to dermatologists but also to industrial medical officers. There has been a noticeable increase in dermatitis among housewives, particularly of dermatitis caused by alkalis and detergents. On the other hand, I find that in the factories under my supervision there has been no increase in dermatitis among workers exposed to steam (as in plating-shops), and among canteen workers and others whose occupation necessitates the hands being in water for long periods or their using solvents or detergents which are soluble in water. Rubber gloves have never been considered satisfactory, particularly where instruments have to be handled or where the rubber marks glassware. The use of barrier creams is enforced throughout this organisation, but it must be emphasised that a variety of barrier creams are used, each covering specific risks against acids, alkalis, and organic materials. Education of the workers in the correct method of use is essential.

The hands should, I suggest, be treated late at night with an emollient cream. I have found that treating the hands after exposure to the risk is not a very satisfactory procedure. It is better to rely upon prevention with a barrier cream, and to see that it is regularly used through supervision by nurses and factory personnel.

It seems to me that to expect a woman to confine her domestic activities, even for a while, to the less hazardous job of drying is almost impossible in most households.

A. C. Cossor Ltd.,
Highbury Grove, London, N.5.

L. B. BOURNE
Senior Medical Officer.

SIR,—I wonder how many of your readers would confess, like me, that they do not use any "detergent" for washing up? Plain hot water and a mop on a stick comprise the outfit.

Hove, Sussex.

G. M. WAUCHOPE.

Notes and News

MEDICAL POSTS IN SYRIA

THE medical faculty of the Syrian University, Damascus, is seeking British candidates for the vacant posts of assistant professor of anæsthetics, anatomy, physiology, biochemistry, and histology and pathology. The faculty has been considerably developed since the war in the face of serious difficulties, chiefly lack of accommodation and equipment. Much progress has been made in the last four years; new premises have been taken over and much new equipment has been bought from Britain, France, and the U.S.A. The teaching staff includes eleven Syrian professors, under the head of the faculty. There is at present no British professorial staff, but there are a British matron and three British nursing sisters at the teaching hospital. Courses in pharmacy (five years) and dentistry (four years) are run in addition to the six-year courses of medical studies. There are 450–500 students.

Teaching facilities, at present limited, are constantly being expanded, and lecturers engaged from abroad are given considerable scope to choose and buy necessary equipment. The faculty buildings include laboratories of histology and pathological anatomy, physiology, biology (animal and vegetable), medical and general chemistry, and bacteriology; a theatre of anatomy and dissection; and a medicolegal institute. Great efforts are being made by the Syrian authorities to ensure that medical teaching is of the highest quality and to raise the standard of the health service. These posts are an important element in their programme, and the British doctors appointed to them will, therefore, be able to make a real contribution to the welfare of the country.

Inquiries about terms of engagement and living conditions should be addressed to the Middle East Secretariat, Foreign Office, London, S.W.1, who will be glad to see anyone requiring further information about these posts.

FOR RELATIVES OF THE MENTALLY ILL

MENTAL breakdown in a member of a family is a bewildering and terrible experience for the relatives. Many of them know nothing about modern forms of treatment, or the régime of care and reablement now established in all good mental hospitals. Crichton Royal, Dumfries, has just published a short clear guide for patients' relatives and friends, explaining that a patient may need to be admitted to hospital in order to protect him from disturbing circumstances (among which must be classed familiar surroundings), and to protect him from suicidal impulses. Relatives are advised to let patients settle down before coming to visit them, but are told that after that visits are welcome and helpful in most cases, and that patients may send and receive letters freely unless the relatives or doctor think it unwise. The brochure explains how the psychiatrist assesses the illness (by physical examination, laboratory investigations, and history-taking); how the patient will spend his days, and how occupation, recreation, relaxation, and possibly hydrotherapy can help him; what amenities in the way of games, excursions, library, and entertainment are offered; and what religious services are held. Special treatments, such as psychotherapy, insulin treatment, electrical convulsive treatment, prolonged narcosis, and prefrontal leucotomy, are briefly and fairly described, and there are reassuring final paragraphs on convalescence and the return home.

Without raising any false hopes this little guide gives an encouraging and truthful picture of modern mental-hospital care, and should help to allay the anxiety and distress which relatives inevitably suffer. The idea might well be adopted by all mental hospitals.

WHITAKER 1950

THE serious student of any recent epoch of English social life always turns to *Punch* for the subjective flavour of his period. For its objective background he could have no better reference book than the appropriate volumes of Whitaker, and the 1950 almanack[1] continues to reflect faithfully the variety and limitations of our national life. On its hospitable pages you will find the orders of chivalry and the Olympic records, the friendly societies and the learned societies, the stellar system and the metric system. This comprehensiveness sometimes makes strange page-mates; for instance, under the longest bridges stand the seven cardinal virtues and the seven mortal sins, while seasonable and unseasonable fish adjoin the compound-interest tables. But it is very nearly impossible to fail to find the information you want, somewhere in Whitaker, and it is quite impossible to dip into it anywhere without finding something of interest.

KIND KILLING

A LEAFLET to guide those who have to destroy animals without expert help has been compiled on behalf of the Universities Federation for Animal Welfare.[1] The leaflet contains clear instructions for dealing with domestic and other animals, fish, and birds.

University of Cambridge

On Feb. 10 the degrees of M.B., B.CHIR. were conferred by proxy on K. P. Abel and I. F. Bishop.

University of Leeds

On Feb. 17 Sir Alexander Fleming, F.R.S., was presented with a Wood gold medal, which under the terms of the will of Mr. Hoffman Wood, a Leeds architect, was awarded for "the most successful discovery for the relief of human pain and suffering."

University of Sheffield

Lord Boyd-Orr, F.R.S., will deliver the fourth Basil Hicks lecture on Friday, Nov. 10.

Dr. E. W. Clarke has been appointed assistant lecturer in physiology, Dr. F. N. Ghadially assistant lecturer in pathology, and Dr. R. A. Trevethick honorary lecturer in industrial medicine.

Royal College of Surgeons of England

On March 22, 1800, King George III granted a charter to the "Royal College of Surgeons in London"; and at the Buckston Browne dinner on Feb. 15, Sir Cecil Wakeley, president of the college, said that this year there would be various celebrations to mark the 150th anniversary. Sir Cecil began his report on the activities of the last twelve months by referring to Lord Nuffield's gift of £250,000 which is to be used for the construction of the Nuffield College of Surgical Sciences. This gift, he said, was a fitting climax to the eight years' wonderful work by his predecessor, Lord Webb-Johnson. Plans for the new college and for reconstructing the existing college were now far advanced. There was a tremendous demand for the facilities offered by the college; and during the past year some sixty to seventy thousand pounds had been spent on teaching and research. Fees charged to students could not cover the cost: and it should be possible for the college to obtain a grant. In welcoming the guests, Sir Harry Platt spoke with regret of Sir Wilson Jameson's retirement from the post of chief medical officer at the Ministry of Health: "If he is to cultivate his garden and to reduce his handicap at golf, somebody must see to it that it is only at the weekends." In replying, Sir Wilson surveyed his years at the Ministry, contrasting the conditions in war and in peace. During the war the Emergency Medical Service ("the exact make-up of which no-one really understood") worked because people were determined to make it work. With the return of peace, life became more complicated: action gave way to discussion, and the atmosphere became tinged with politics. At the moment things were easier: there was no Parliament; "I've hardly got a Minister"; and even the British Medical Association was in a resting phase with its secretary away electioneering. Air Marshal P. C. Livingston, who also spoke for the guests, mentioned the prevailing difficulty of filling civil appointments abroad. Often the salaries offered were good, and undoubtedly the filling of such appointments with British doctors would be a good advertisement for this country; yet, because the appointments were for limited periods and loss of status on return to this country was feared, candidates were few. The toast of The College was proposed by General Sir Bernard Paget, a grandson of Sir James Paget, president of the college in 1875. As a soldier, Sir Bernard attributed the reduced mortality from wounds in the late war partly to improved tactics and training; but medicine had played a great part. "I do not think there is any other field of human activity in which more beneficent progress is being made."

Faculty of Homœopathy

On Thursday, March 2, at 5 P.M., at the Royal London Homœopathic Hospital, Mr. C. Naunton Morgan will give an address on Rectal Surgery.

University College Hospital Medical School

Prof. F. G. Young, F.R.S., will deliver the Sydney Ringer lecture at the school, University Street, London, W.C.1, on Thursday, March 16, at 4.30 P.M. He is to speak on the Experimental Approach to the Problem of Diabetes Mellitus.

Empire Rheumatism Council

Lord Webb-Johnson has been elected a vice-president of the council in place of the late Sir Henry McMahon. He has also accepted the position of vice-chairman of council in place of Sir Walter Kinnear, who has resigned on grounds of health.

British Health Resorts Association

A meeting of this association will be held today, Friday, Feb. 24, at 4 P.M., at 11, Chandos Street, London, W.1.

Royal Statistical Society

The council of this society are offering the Frances Wood prize (value £30) for the best investigation, on statistical lines, of any problem bearing directly or indirectly upon the economic or social conditions of the people. Competitors must be under 30 on Jan. 1, 1950. Further information may be had from the honorary secretaries of the society, 4, Portugal Street, London, W.C.2.

International Conference on Pneumoconiosis

The following have been nominated by the Government to attend a conference of experts on pneumoconiosis, arranged by the International Labour Office, which is being held at Sydney, New South Wales, from Feb. 28 to March 11, 1950: Dr. E. R. A. Merewether, H.M. senior medical inspector of factories; Dr. J. C. McVittie, member of the Swansea pneumoconiosis medical board; Dr. C. M. Fletcher, director of the Pneumoconiosis Research Unit, Cardiff; and Mr. E. A. Shearing, assistant secretary, Ministry of Fuel and Power.

Hunterian Society

At this society's annual dinner in London on Feb. 16, Dr. W. Thomson Brown, the president, reported that the society, founded 26 years after John Hunter's death, was flourishing and increasing in numbers. Its members included the shy and the bold, the young and the old, general practitioners and consultants who derived pleasure and profit from meeting. The whole value of these meetings was often not immediately apparent; for it might not be until the next morning that the apt criticism or the new idea came to mind. The presidents, each of whom served for one year, were chosen in turn from surgeons, physicians, and general practitioners; and as a general practitioner, absorbed and isolated in his practice, Dr. Thomson Brown testified to the society's value in enabling him to lift his eyes and contemplate larger fields. The president was replying to the toast of The Society, proposed by the Bishop of London, who had spoken of the growing unison, in these days of psychotherapy, between clergyman and doctor. The value of the society, in his eyes, was that it promoted free discussion and encouraged those who spoke to improve their style. (This, he added in parenthesis, would have appealed to John Hunter, who, it seemed, could hardly read or write at the age of 21.) The medical profession had included many distinguished men of letters; prominent among these were Henry Vaughan (1622–1695), the poet, and Sir Thomas Browne (1605–1682), author of *Religio Medici*, in his opinion the best prose book of all time. Toasting the Lord Mayor and Corporation of the City of London, Mr. A. E. Roche referred to the society's close ties with the city. Sir Cecil Wakeley and Mr. C. R. Havers, K.C., replied for the guests to a toast proposed by Mr. J. C. Ainsworth-Davies. Sir Cecil praised the society's habit of meeting for dinner before its discussions; for this not only promoted good fellowship but fitted the fellows for the discussion which followed. Sir Cecil went on to say that whichever political party gained power, there would soon be placed on the statute-book a law by which young doctors would have to serve one year in a hospital before they were registered. The wisdom of this measure he did not dispute; but where, he asked, were these doctors to be accommodated?

The society's gold medal was presented to Dr. S. M. Rivlin for his essay on the Treatment of Varicose Veins and their Complications.

[1] Kind Killing. Compiled by F. Jean Vinter, technical secretary of UFAW. Obtainable from UFAW, 284, Regent's Park Road, London, N.3. Pp. 12. 3d.

and which we hope to publish very shortly, there are indications that this state of affairs does not prevail today. For this reason, not only sound basal immunity but antitoxic values far above the Schick level must be aimed at in the immunisation of young children, if the need for numerous boosting doses is to be avoided.

Any conclusions about the suitability of the Schick-negative state as a criterion for safety against clinical diphtheria can only have been drawn in the past, when there were epidemics; then the antitoxic values of the population were receiving intermittent boosts and were actually considerably above the Schick level. The fate, on exposure to infection, of people with antitoxic values only just above the Schick level is not known; but the high incidence of diphtheria among adults in epidemics in the occupied countries during the war, suggests that their antitoxic values had fallen in the absence of recent natural stimulation, and consequently they were inadequately protected by the basal immunity conferred by immunisation in childhood. It should be our aim to act on this experience, and attempt to immunise young children in such a way that reasonably good antitoxic titres are maintained into adult life.

Dr. Bousfield has done much valuable work with the aid of the Schick test, but I am convinced that a higher standard than the Schick-negative state is now required.

Finally, I hope that Dr. Bousfield was referring to boosting doses when he mentioned single-injection prophylaxis. Both the antitoxic response and the duration of antitoxic immunity increase with the number of injections given, and in these days when "natural boosts" are almost negligible, these factors are of the utmost importance.

MOLLIE BARR.

ON WASHING THE DISHES

SIR,—Your timely annotation last week is of considerable interest not only to dermatologists but also to industrial medical officers. There has been a noticeable increase in dermatitis among housewives, particularly of dermatitis caused by alkalis and detergents. On the other hand, I find that in the factories under my supervision there has been no increase in dermatitis among workers exposed to steam (as in plating-shops), and among canteen workers and others whose occupation necessitates the hands being in water for long periods or their using solvents or detergents which are soluble in water. Rubber gloves have never been considered satisfactory, particularly where instruments have to be handled or where the rubber marks glassware. The use of barrier creams is enforced throughout this organisation, but it must be emphasised that a variety of barrier creams are used, each covering specific risks against acids, alkalis, and organic materials. Education of the workers in the correct method of use is essential.

The hands should, I suggest, be treated late at night with an emollient cream. I have found that treating the hands after exposure to the risk is not a very satisfactory procedure. It is better to rely upon prevention with a barrier cream, and to see that it is regularly used through supervision by nurses and factory personnel.

It seems to me that to expect a woman to confine her domestic activities, even for a while, to the less hazardous job of drying is almost impossible in most households.

A. C. Cossor Ltd.,
Highbury Grove, London, N.5.

L. B. BOURNE
Senior Medical Officer.

SIR,—I wonder how many of your readers would confess, like me, that they do not use any "detergent" for washing up? Plain hot water and a mop on a stick comprise the outfit.

Hove, Sussex.

G. M. WAUCHOPE.

Notes and News

MEDICAL POSTS IN SYRIA

THE medical faculty of the Syrian University, Damascus, is seeking British candidates for the vacant posts of assistant professor of anæsthetics, anatomy, physiology, biochemistry, and histology and pathology. The faculty has been considerably developed since the war in the face of serious difficulties, chiefly lack of accommodation and equipment. Much progress has been made in the last four years; new premises have been taken over and much new equipment has been bought from Britain, France, and the U.S.A. The teaching staff includes eleven Syrian professors, under the head of the faculty. There is at present no British professorial staff, but there are a British matron and three British nursing sisters at the teaching hospital. Courses in pharmacy (five years) and dentistry (four years) are run in addition to the six-year courses of medical studies. There are 450–500 students.

Teaching facilities, at present limited, are constantly being expanded, and lecturers engaged from abroad are given considerable scope to choose and buy necessary equipment. The faculty buildings include laboratories of histology and pathological anatomy, physiology, biology (animal and vegetable), medical and general chemistry, and bacteriology; a theatre of anatomy and dissection; and a medicolegal institute. Great efforts are being made by the Syrian authorities to ensure that medical teaching is of the highest quality and to raise the standard of the health service. These posts are an important element in their programme, and the British doctors appointed to them will, therefore, be able to make a real contribution to the welfare of the country.

Inquiries about terms of engagement and living conditions should be addressed to the Middle East Secretariat, Foreign Office, London, S.W.1, who will be glad to see anyone requiring further information about these posts.

FOR RELATIVES OF THE MENTALLY ILL

MENTAL breakdown in a member of a family is a bewildering and terrible experience for the relatives. Many of them know nothing about modern forms of treatment, or the régime of care and reablement now established in all good mental hospitals. Crichton Royal, Dumfries, has just published a short clear guide for patients' relatives and friends, explaining that a patient may need to be admitted to hospital in order to protect him from disturbing circumstances (among which must be classed familiar surroundings), and to protect him from suicidal impulses. Relatives are advised to let patients settle down before coming to visit them, but are told that after that visits are welcome and helpful in most cases, and that patients may send and receive letters freely unless the relatives or doctor think it unwise. The brochure explains how the psychiatrist assesses the illness (by physical examination, laboratory investigations, and history-taking); how the patient will spend his days, and how occupation, recreation, relaxation, and possibly hydrotherapy can help him; what amenities in the way of games, excursions, library, and entertainment are offered; and what religious services are held. Special treatments, such as psychotherapy, insulin treatment, electrical convulsive treatment, prolonged narcosis, and prefrontal leucotomy, are briefly and fairly described, and there are reassuring final paragraphs on convalescence and the return home.

Without raising any false hopes this little guide gives an encouraging and truthful picture of modern mental-hospital care, and should help to allay the anxiety and distress which relatives inevitably suffer. The idea might well be adopted by all mental hospitals.

WHITAKER 1950

THE serious student of any recent epoch of English social life always turns to *Punch* for the subjective flavour of his period. For its objective background he could have no better reference book than the appropriate volumes of Whitaker, and the 1950 almanack[1] continues to reflect faithfully the variety and limitations of our national life. On its hospitable pages you will find the orders of chivalry and the Olympic records, the friendly societies and the learned societies, the stellar system and the metric system. This comprehensiveness sometimes makes strange page-mates; for instance, under the longest bridges stand the seven cardinal virtues

BLOOD pH AND BLOOD-FLOW DURING MUSCULAR ACTIVITY*

KLOTHILDE GOLLWITZER-MEIER
M.D. Munich
PROFESSOR OF PATHOLOGICAL PHYSIOLOGY IN THE UNIVERSITY OF HAMBURG

IN spite of the numerous experiments made on isolated frog-muscle preparations to study the relation between the chemical changes of muscular contraction and their mechanical effects, many problems remain unsolved. In fact, the problems have become more complicated from year to year, and it might appear doubtful whether experiments on a more elaborate preparation, such as the mammalian skeletal muscle in situ, would be more suitable for studying this intricate relationship. Nevertheless, attempts of this kind have been made again and again because such experiments offer certain advantages. It is possible to examine the blood flowing to and from the muscle. Further, the muscle remains under the influence of all the nervous, hormonal, and respiratory changes which occur in the animal and by affecting the vascular reactions in the muscle, adjust its blood-supply to its metabolic requirements.

There is one important problem which can be studied under these conditions only and has never been satisfactorily settled—i.e., the relation between blood pH and the blood-flow in an active muscle. Our experiments are concerned with this question and the results show conclusively that the blood pH is not the sole or even the main factor responsible for the vascular reactions occurring in a muscle in situ during and after muscular activity.

Our experiments were made on the dog's gastrocnemius muscle in situ with its normal circulation intact, but with every branch of the femoral artery and vein not going to, or coming from, the gastrocnemius carefully tied so that the blood in the femoral vein could be regarded as coming from the gastrocnemius only. The dogs were anæsthetised with chloralose and heparinised. The peripheral end of the cut sciatic nerve was stimulated electrically with alternating current from a Philips "Schwebungs-Oscillator" with a phase frequency of 100 hertz per sec. Submaximal contractions were obtained with a current intensity of 0·5–1 mA.

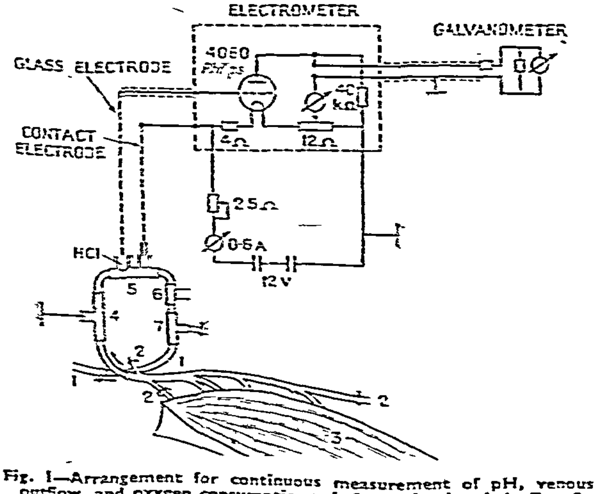

Fig. 1—Arrangement for continuous measurement of pH, venous outflow, and oxygen consumption: 1, femoral vein, tied off at 2; 3, gastrocnemius muscle; 4, earthed brass tube; 5, glass electrode; 6, oxygen cell; 7, hot-wire arrangement.

Two different groups of experiments were performed. In the first group the nerve was stimulated for a single period of 2–60 sec. to produce a single tetanic contraction. In the second group the nerve was stimulated every other second for 3–8 minutes to produce a series of rhythmic tetanic contractions. The results of the two groups of experiments will be discussed separately.

METHOD FOR CONTINUOUS MEASUREMENT OF BLOOD pH IN THE LIVING ANIMAL

The experiments required continuous measurements of the blood pH in the living animal. The general arrangement and the special features of the method used can be seen from fig. 1. The pH had to be taken outside the animal body. For this purpose a short loop consisting of glass, brass, and rubber parts was inserted into the two ends of the divided femoral vein. The blood pH was taken from the inside of this loop with a glass electrode connected to a valve electrometer and registered with a Rubstrat-Göttingen galvanometer. The blood had to be earthed before entering the part of the loop containing the glass electrode; this was accomplished by letting the blood pass through an earthed brass tube 5 cm. long. The electrometer and the connections to the galvanometer also had to be earthed. The electrometer was shielded by being installed in an earthed metal box. The connections between the glass electrode and the electrometer were metal wires supported by insulating amber inside an earthed metal tube or high-frequency cable. The MacInnes glass electrodes were manufactured by our glass blower and made from special Jena glass (Schott & Gen. 4073/III). The electrode was filled with N/10 HCl, and contact was made through a calomel electrode. The speed of the response of the whole measurement was 2–3 sec. and the accuracy was ± 0·02 pH.

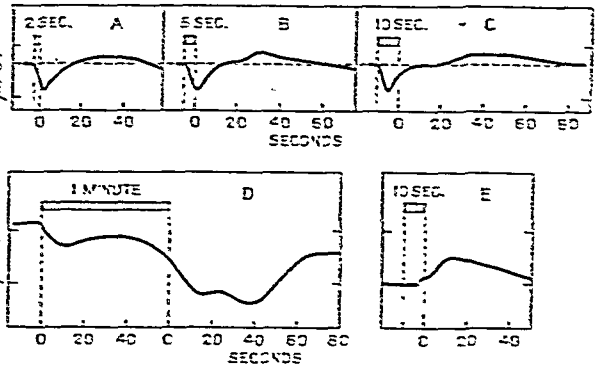

Fig. 2—Changes in pH of blood in femoral vein during and after tetanic contraction of gastrocnemius muscle lasting: (A) 2 sec., (B) 5 sec., (C) 10 sec., and (D) 60 sec. (E) muscle poisoned with mono-iodoacetic acid.

EFFECTS OF A SINGLE TETANIC CONTRACTION

Blood pH

The venous blood from the isotonically contracted gastrocnemius muscle showed three distinct changes in blood pH: (1) an initial short phase of acidity, followed by (2) a longer-lasting phase of alkalinity, and finally by (3) a protracted persistent phase of acidity. Results obtained with different periods of stimulation are shown in fig. 2.

With a contraction lasting 2 sec. (fig. 2A) the reaction shifts immediately towards the acid side, but the lowest point of acidity is reached a few seconds after the end of tetanus. The subsequent alkaline phase is faint and reaches its maximum 30 sec. after tetanus. The third phase is not distinct after such a brief contraction.

---

* Lecture given at King's College, London, on May 18, 1949.

York Medical Society

At a meeting of this society to be held on March 4, Dr. C. W. Curtis-Bain will read a paper on Angina Pectoris. On March 18 Prof. Margaret Fairlie will speak on Hormones.

Number of Pharmacists

The number of pharmacists rose last year to 25,662, the largest number there has ever been. The increase of 214 was more than double that of 1948, and is the biggest increase since 1939.

South-Wales Medical Ex-Service Association

This association will hold their annual reunion dinner on Saturday, March 4, at the Park Hotel, Cardiff, at 7.45 P.M. Tickets (price 12*s.* 6*d.*) may be had from the hon. secretary, Mr. C. W. D. Lewis, surgical unit, Royal Infirmary, Cardiff.

Professor F. M. Burnet, F.R.S., director of the Walter and Eliza Hall Institute, who is visiting this country in the spring, will deliver the Croonian lecture for 1950 to the Royal Society on June 15.

Dr. Benjamin Viel, professor of hygiene and preventive medicine in the University of Chile, Santiago, is spending two months in this country under the auspices of the British Council to study the National Health Service in operation.

CORRIGENDUM : *Antigen-antibody Reactions.*—In this article by Dr. F. Stratton (Feb. 11, p. 247) the first sentence of the summary should read : "A method is described of using an anti-rabbit serum prepared in hens with sensitised sheep cells as an indicator to detect rabbit serum."

Diary of the Week

FEB. 26 TO MARCH 4

Monday, 27th

UNIVERSITY OF LONDON
5.30 P.M. (London School of Hygiene, Keppel Street, W.C.1.) Prof. J. W. Bigger : Synergism and Antagonism in Relation to Antibacterial Substances.
5.30 P.M. (University College, W.C.1.) Prof. Jerzy Neyman (University of California) : Statistical Problems Connected with Medical Diagnosis. (First of three lectures.)
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Mr. A. Dickson Wright : Surgical Aspects of Hyperpiesia. (Second Lettsomian lecture.)
HUNTERIAN SOCIETY
8.30 P.M. (Mansion House, E.C.4.) Dr. D. T. Davies : John Hunter—the Man and his Message. (Hunterian oration.)

Tuesday, 28th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. E. M. Evans : Fractures of the Radius and Ulna. (Hunterian lecture.)
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. I. Muende : Fungus Diseases of the Skin.

Wednesday, 1st

INSTITUTE OF PSYCHIATRY
4.30 P.M. (Maudsley Hospital, S.E.5.) Dr. E. Stengel : Postgraduate lecture-demonstration.
MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH
8.30 P.M. (Royal College of Surgeons, 18, Nicolson Street.) Dr. Douglas Nicholson : The Rheumatic Problem in Childhood.
UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Dr. D. Christison : *Prognosis in Iridocyclitis.*

Thursday, 2nd

ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. B. Windeyer, Mr. C. P. Wilson : Treatment of Malignant Disease of the Paranasal. (Otolaryngology lecture.)
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Dr. Anthony Feiling : Neurology lecture-demonstration.
INSTITUTE OF DERMATOLOGY
5 P.M. Dr. D. I. Williams : Exfoliative Dermatitis with Special Reference to BAL (dimercaprol).

Friday, 3rd

MAIDA VALE HOSPITAL MEDICAL SCHOOL, W.9
5 P.M. Dr. Douglas McAlpine : Neurological demonstration.
ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh
8 P.M. Sir Edward Mellanby, F.R.S. : Widespread Nerve Degeneration Due to Abnormal Bone Growth.

Saturday, 4th

BRITISH ASSOCIATION OF PHYSICAL MEDICINE
10.30 A.M. (St. Margaret's School, Coombe Road, Croydon.) Dr. J. H. Crosland : Treatment of Cerebral Palsy.

Appointments

BLAIR, R. A., M.D. Lond., D.P.M. : consultant psychiatrist, Cane Hill Hospital, Coulsdon, Surrey.
BRUZAUD, J. D., M.R.C.S. : appointed factory doctor under the Factories Acts, Duffield district.
CAMPBELL, C. G. H., M.A., M.D. Camb., D.P.H. : senior asst., department of venereal diseases, London Hospital.
COCKREM, GWENDOLINE, M.R.C.S., M.R.C.O.G. : consultant obstetrician and gynæcologist, hospitals in Dewsbury, Batley, and Mirfield area.
FITTON, J. M., M.B. Leeds, F.R.C.S. : consultant orthopædic surgeon, hospitals in Dewsbury, Batley, and Mirfield area.
GALLAGHER, EVA, M.B. Lpool : senior asst, department of venereal diseases, London Hospital.
* GRAF, K. A., M.D. Vienna, D.P.M. : asst. psychiatrist, Brentwood Mental Hospital, Essex.
GROARKE, F. L., M.B. N.U.I., D.P.H., D.C.H. : M.O.H., Brightlingsea, Clacton, Frinton, Walton, and Tendring, and asst. county M.O.H., Essex.
HALL, R. A., M.B. Leeds, F.R.C.S. : consultant general surgeon, York A and Tadcaster hospital group.
HARRIS, C. R., M.B. Dubl., D.P.M. : consultant psychiatrist, Holloway Sanatorium, Virginia Water.
KIRMAN, B. H., M.D. Lond., D.P.M. : consultant psychiatrist, Fountain hospital group, Tooting, London.
MCINTYRE, W. M., M.D. Edin., M.R.C.P.E. : consultant psychiatrist, St. Ebba's Hospital, Epsom.
MCKIDDIE, J. M., M.B.E., M.B. Aberd., M.R.C.O.G. : consultant obstetrician and gynæcologist, hospitals in Wakefield A, Pontefract and Castleford, and Goole, Howden, and Selby areas
MADDEN, STEPHEN, M.B. Leeds, F.R.C.S.E., M.R.C.O.G. : consultant obstetrician and gynæcologist, hospitals in East Riding, Hull A, and Hull B areas.
MONTGOMERY, N. M., M.D. Glasg., D.P.M. : consultant psychiatrist, Storthes Hall Hospital, Kirkburton, Yorks.
NEUSTATTER, W. L., M.D., B.SC. Lond., M.R.C.P. : consultant psychiatrist, St. Ebba's Hospital, Epsom.
NUSSBAUM, ILSE, Staatsexamen Berlin, D.P.M. : consultant psychiatrist, Rainhill Hospital, Lancs.
O'MALLEY, A. G., M.CH.(ORTH.) Lpool, F.R.C.S.E. : consultant orthopædic surgeon, St. Helens Hospital, Lancs.
ROSS, THOMAS, M.B. Glasg., D.P.H. : M.O.H., Walsall.
RYAN, M. J., M.B. Dubl., D.C.H. : asst. county M.O.H., Essex.
STALKER, HARRY, M.D. Edin., F.R.C.P.E., DIPL.PSYCH. : consultant psychiatrist, Cane Hill Hospital, Coulsdon, Surrey.
WEST, H. F., M.D. Lond., M.R.C.P., D.T.M. : physician i/c. Sheffield Centre for Investigation and Treatment of Rheumatism.
WYATT, MABEL, M.D. Lond. : asst. county M.O.H., Essex.

* Amended notice.

Colonial Service :

CHARLES, L. J., M.B. Edin., D.T.M. & H. : chief officer, mosquito control service, British Guiana.
EDMUNDSON, KENNETH, M.B. Lpool : deputy director of medical services, Tanganyika.
GAULD, E. R., M.B. Aberd., M.R.C.P., D.T.M. & H. : physician specialist, Gold Coast.
GOODMAN, LEONARD, F.R.C.S. : gynæcologist, Gold Coast.
GRAHAM, J. L. T., L.R.C.P.I. : M.O., Nyasaland.
HASTINGS, J. M., B.M. *Oxfd* : M.O., British Honduras.
HURLEY, D. W. H. : M.B. N.U.I. : M.O., Kenya.
MAJEKODUNMI, M. A., M.A., M.D. Dubl., D.C.H. : specialist (gynæcology), Nigeria.
NAYLOR, E. G., M.B. St. And. : M.O., Northern Rhodesia.
ROBERTS, M. A. W., M.B. Dubl., F.R.C.S.I. : senior surgical specialist, Nyasaland.
SELBY, J. A. R., M.B. Edin., D.P.H. : senior social-hygiene officer, Hong-Kong.
SHEZLEY, RUPERT, M.D. Lond., D.T.M. & H. : specialist physician, superscale grade B, Federation of Malaya.
SOLTYSIK, ADAM, M.D. Lwow : temporary district M.O., St. Lucia, Windward Islands.
TIMMS, G. L., M.B. Lond. : asst. director of laboratory services, Kenya.
VILAIN, PHYLLIS, M.R.C.S. : M.O., grade B, Trinidad.
WILKINSON, P. B., M.B. Lond., M.R.C.P. : medical specialist, Hong-Kong.
WILSON, THOMAS, M.B. Belf., D.P.H., D.T.M. & H. : senior malaria-research officer, Federation of Malaya.

Births, Marriages, and Deaths

BIRTHS

BATES.—On Feb. 12, the wife of Dr. J. A. V. Bates—a son.
BICKFORD.—On Feb. 6, at West Kirby, Cheshire, the wife of Mr. B. J. Bickford, F.R.C.S.—a daughter.
CUTTING.—On Feb. 9, the wife of Dr. A. H. Cutting—a son.
D'ABREU.—On Feb. 16, in London, the wife of Mr. Frank D'Abreu, F.R.C.S.—a daughter.
FLEMING.—On Jan. 17, at Greenock, the wife of Dr. John Fleming—a daughter.
GORDON.—On Feb. 11, the wife of Dr. I. R. S. Gordon—*a daughter.*
GRIFFITHS.—On Feb. 7, to Dr. G. Audrey Griffiths (*née* Meigh), wife of Dr. A. L. Griffiths—a daughter.
SAMES.—On Feb. 13, the wife of Mr. C. P. Sames, F.R.C.S.—a daughter.

DEATHS

COLDSTREAM.—On Feb. 13, in London, George Probyn Coldstream, M.B. Edin., aged 79.
HELME.—On Feb. 15, Arthur Crofts De Beetham Helme, M.A., M.B. Camb., D.T.M. & H.
HENDERSON.—On Feb. 11, in London, Eleanor Maud Henderson, M.B. Aberd., D.P.H., aged 50.
WIGGIN.—On Feb. 17, at Torquay, Hugh Peter Victor Wiggin, M.R.C.S., aged 79.

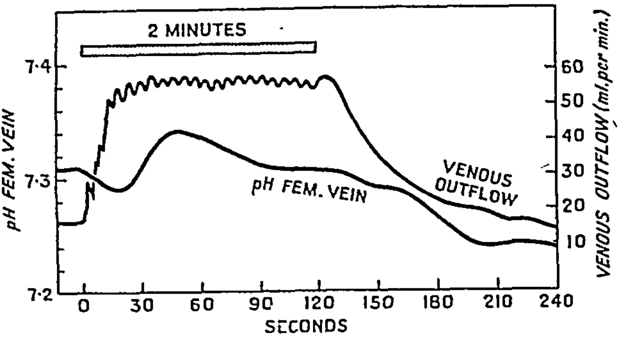

Fig. 5—Changes in blood pH and venous outflow from muscle during rhythmic tetanic contractions (3 min.)

phase and finally by an acid phase. A typical experiment is illustrated in fig. 5. The three phases were observed whether the period of rhythmic stimulation was short or long, but the phases varied in duration and intensity from experiment to experiment even if the duration of stimulation remained constant. Fig. 6 shows such variations in four different experiments, in each of which the duration of stimulation was 4 minutes.

Muscular fatigue prolongs the second alkaline phase and extinguishes the third but not the first acid phase. In fig. 7 the striking difference between a fresh and a partially fatigued muscle is seen in the same animal, in which simultaneously the nerve to the left gastrocnemius was stimulated for the first time and that for the right gastrocnemius for the fourth time. The alkaline phase is distinctly prolonged in the right partially fatigued muscle though the third acid phase is not yet abolished. Later in the same experiment, when the left gastrocnemius was stimulated for the fourth time there was the same change in blood pH as occurred before in the muscle on the right side, and this time the final acid phase was absent.

Blood-flow

Measurements of blood-flow during such series of short periods of tetanic stimulation show certain differences compared with the effects obtained with a single short tetanus. These differences result from the fact that the muscle is stimulated every other second only. A typical result is illustrated in fig. 5. The venous outflow increases and attains within the first 30 sec. a high plateau, which is maintained during the whole period of repeated stimulations. The initial rise does not proceed continuously but is interrupted by short periods of reduced outflow, and there are similar shallow waves during the whole time that the hyperæmia is maintained. These shallow waves represent effects of phases 1 and 2, described for the single tetanus—i.e., expulsion of blood at the beginning of each single 1-sec. tetanus and diminution of blood-flow by vasocompression from the contracting muscle. As will be seen, however, these waves are not synchronous with each 1-sec. tetanus in such a series. This is because, from the second or third tetanus onwards, phases 3 and 4 of the preceding, and phase 1 of the following, tetanus become superimposed.

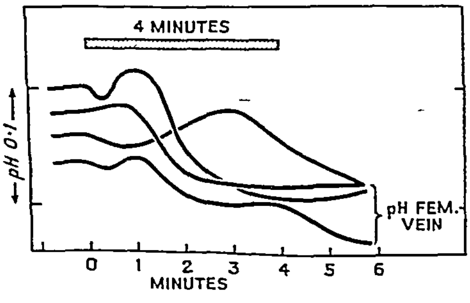

Fig. 6—Variations in blood pH, in different experiments, during 4 minutes' rhythmic tetanic contractions.

Though there are no indications of an insufficient blood-supply during such repeated tetanic stimulations, there is always a slight increase in blood-flow immediately afterwards, and for 5–10 sec. the flow is greater than the average flow measured during the period of stimulation. This indicates a short overshooting of the vasodilatation in the relaxed muscle. The blood-flow then decreases rapidly, and after a few minutes may be even less than it was before stimulation.

Consumption of Oxygen

The utilisation of oxygen increases only slightly in the muscle during rhythmic tetanic stimulations because of the continuous hyperæmia. The consumption of oxygen, however, increases rapidly and reaches a steady state after the first minute. A certain oxygen debt nevertheless accrues during the following minutes of stimulation even *if the muscle is not working too hard. This is evident* from the increased consumption of oxygen which persists for 1–4 minutes when stimulation has come to an end. In the fatigued muscle the consumption of oxygen during the repeated tetanic stimulations is less than in the fresh muscle. This corresponds to the reduced blood-supply of the tired muscle, and in our experiments was partly caused by the lowering of arterial blood-pressure which occurred in the course of the experiment.

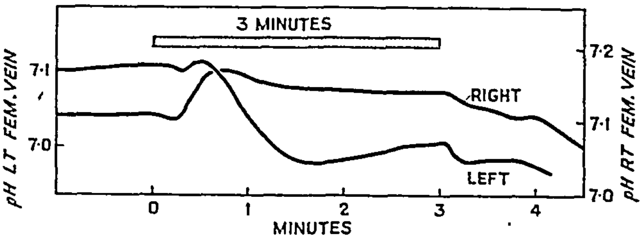

Fig. 7—Effect of fatigue on changes in pH of venous blood caused by 3 minutes' rhythmic tetanic contractions (right gastrocnemius fatigued, left fresh).

Lactic Acid

The concentration of lactic acid in the outflowing venous blood is of special interest. During a series of rhythmic tetanic stimulations the level rises from the beginning to the end of stimulation. The rise proceeds at first very quickly and continues later more slowly. At the end of the series of stimulations the concentration does not decrease immediately but for 3–5 minutes even surpasses the highest level reached during stimulation. It then declines and reaches its original level within 10–15 minutes.

From the arteriovenous difference in the concentration of lactic acid and from the blood-flow the amount of lactic acid passing from the active muscle into the blood has been calculated. The increase during a series of tetanic stimulations is considerable and in some experiments amounted to 30–40 mg. If the stimulation lasts longer than 2 minutes, the maximal output of lactic acid occurs during the period of stimulation; otherwise it is not reached until after the cessation of stimulation. The output of lactic acid then decreases again rapidly, and the blood-flow diminishes at the same time.

EXPERIMENTS ON RESTING MUSCLE

In the course of our experiments several factors were examined in resting muscle. Among these adrenaline, acetylcholine, oxygen lack, and passive stretching of the muscle deserve special mention.

With a contraction lasting 5–10 sec. (fig. 2B and C) the lowest point of acidity is reached during the period of tetanic contraction, but the second alkaline phase does not develop before the contraction is over. The third phase is not yet distinct.

With longer periods of stimulation the alkaline phase tends to fall more and more into the period of tetanic contraction. During a contraction lasting 60 sec. (fig. 2D) the first acid phase is over within 10 sec., and the whole alkaline phase falls in the period of tetanic contraction. It is followed by a pronounced third acid phase. Still longer periods of tetanus bring even this phase within the period of contraction.

These results show that the three phases are not related to the duration of a contraction, and that the effect is fundamentally the same in short and long periods of tetanus.

When a muscle becomes fatigued in the course of an experiment, the acidity of the third phase disappears; the change in the blood pH is then characterised by a fairly uniform and long-lasting alkalinity. Similarly, the third acid phase disappears when the muscle has been poisoned with mono-iodoacetic acid (fig. 2E). The final phase of acidity is also lacking when the muscle undergoes tetanic contractions in oxygen lack (fig. 3); the initial phase of acidity may still develop in this condition. The alkaline phase becomes more pronounced with each successive tetanus produced during oxygen lack.

Mention must be made of the changes in the utilisation and consumption of oxygen in the fatigued and in the non-fatigued muscle. The *utilisation of oxygen* is greatly increased in the non-fatigued muscle during tetanus and decreased afterwards. In the fatigued muscle in which the third phase of acidity is absent the exchange of oxygen is so slow that the utilisation of oxygen is hardly changed during the tetanic contraction. The consumption of oxygen in a non-fatigued muscle reaches a peak during, or shortly after, the tetanic contraction. For a short time afterwards the consumption of oxygen remains high, but it then falls rapidly to its previous level. This is completely different from the conditions in the fatigued muscle. Here there occurs only a slight and slow increase during the contraction and afterwards the consumption of oxygen falls even below its original value.

Venous Blood-flow

Changes in venous blood-flow have been measured with the hot-wire anemometer (Anrep and Downing 1926). This method has the advantage of registering very rapid changes. Four phases of muscular outflow could be distinguished during a single tetanic contraction (fig. 4): (1) at the beginning of tetanus there is an initial increase lasting 1–2 sec., caused by the expulsion of blood from the vascular bed of the muscle; (2) there follows a diminution in outflow lasting 5–8 sec. in which the blood-flow may stop completely, and which is due to vasocompression by the contracting muscle; (3) during prolonged tetanus there is an increase in blood-flow due to active local vasodilatation in the muscle which overcomes the compression of the intramuscular vessels (this hyperæmia lasts as long as the contraction and can be considerable, depending on a sufficient aortic pressure); and (4) starting at the beginning of relaxation and associated with it there is a short augmentation of blood-flow, followed by the prolonged hyperæmic after-effect, the duration of which varies greatly and during which the blood-flow is even a little greater than the maximal blood-flow during tetanus.

The second phase of diminution of outflow has been discussed by Anrep and von Saalfeld (1935) and Rein et al. (1935). The problem was taken up by Kramer and Quensel (1937), whose results are in full agreement with ours. With a short tetanus the decrease in outflow is certainly the most striking effect. The blood-flow may even stop. But during a more prolonged tetanus the active local vasodilatation will overcome the compression of the intramuscular vessels, as Rein *et al.* (1935) rightly concluded. According to Anrep and von Saalfeld (1935) such increases in blood-flow during prolonged tetanus are only possible if the muscle is partially *contracted*; the increase in blood-flow is thought to be restricted to the relaxed muscle-fibres. It is doubtful whether this view is correct. The increase in utilisation of oxygen, and particularly the fact that this increase remains fairly high in spite of the increased blood-flow, suggest that all the blood passing through the muscle comes into close contact with the places where the consumption of oxygen is increased.

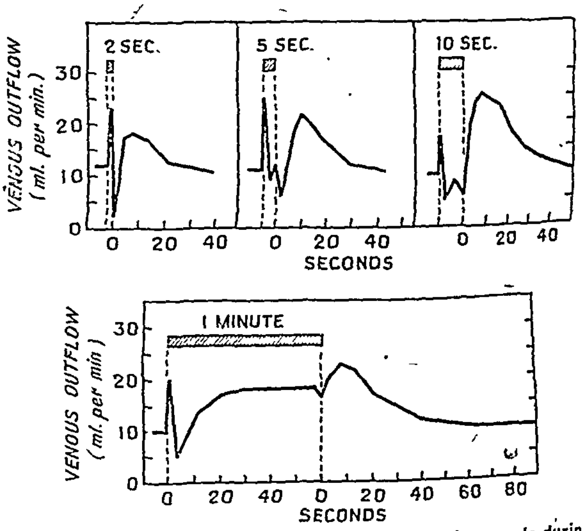

Fig. 4—Changes in venous outflow from gastrocnemius muscle during different periods of tetanic contractions.

There is thus an intense and active dilatation of the blood-vessels in a *contracting muscle* during prolonged tetanus. The mechanisms by which this *vasodilatation may* be brought about are discussed below.

EFFECTS OF STIMULATION FOR 1 SECOND REPEATED EVERY OTHER SECOND

Blood pH

A series of short tetanic *stimulations* produce essentially the same changes in the pH of the venous blood as have been described for a single short tetanus. There is again an initial phase of acidity followed by an alkaline

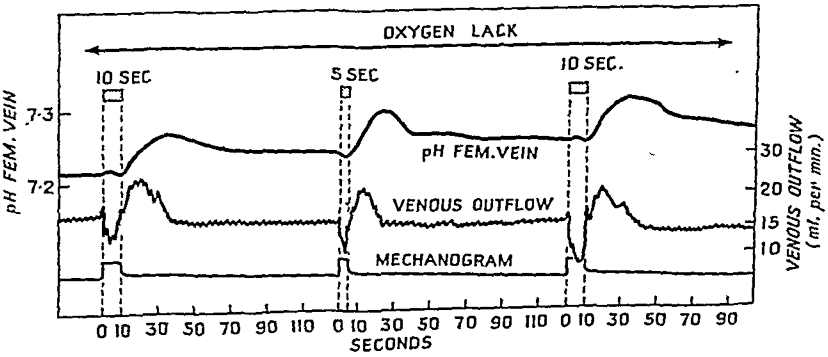

Fig. 3—Three periods of tetanic contraction (10 sec., 5 sec., and 10 sec.) during protracted oxygen lack, showing shifting of blood pH to alkaline side.

brought about in this way was at most about a tenth of that occurring during muscular activity. Clear-cut as these results were, they did not weaken the conception of the rôle of acid metabolites held by most physiologists. One reason was that in those experiments the increase in carbon dioxide and hydrogen concentration in the blood would naturally affect the arteries and arterioles first before reaching the capillaries. This criticism does not apply to our experiments, in which the change in blood pH was brought about by the muscular activity itself and would therefore directly affect the capillary lake.

We limit our discussion to the experiments in which the muscle was stimulated every other second, because in this condition there was no phase in which the blood-flow became severely restricted by vascular compression. If we consider the time relations between the changes in blood-flow and blood pH in these experiments, it becomes clear that the increased blood-flow, which starts simultaneously with the first contractions and is then maintained at a steady level while the contractions last, cannot be the outcome of the changes in blood pH. It is doubtful whether the initial acidity plays more than an insignificant rôle in the increased blood-flow, and the subsequent alkalinity can certainly be of no consequence in the adaptation of the blood circulation to the requirements of the working muscle. Since the nerves were cut and the muscle was stimulated indirectly, proprioceptive reflexes are naturally excluded in our experiments. There remain thus only the following three possibilities to explain the initial vasodilatation: the effect of vasodilator metabolites; the massaging effect of the contracting muscle; and the activation of axon reflexes. These three factors may naturally work in unison.

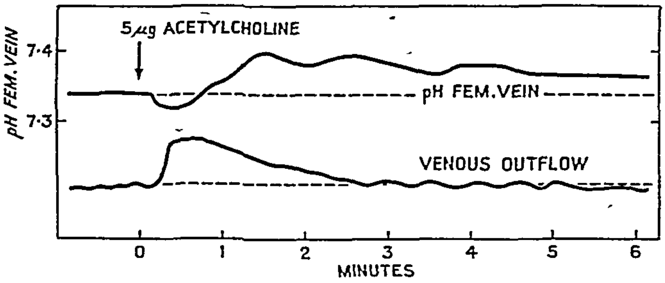

Fig. 10—Effect of injection of 5 µg. of acetylcholine into femoral artery on pH of venous blood and on venous outflow.

The third phase of the blood pH, that of persistent acidity, may well have to be considered as a contributory factor in maintaining the increased blood-flow in the muscle, but our results furnish no evidence to support this view. In most of our experiments we saw no sign of further vasodilatation when the blood pH shifted to the acid side; the blood-flow remained at its high steady level and apparently did not respond to the change in blood pH. Thus, so far at least, our experiments have unfortunately not provided any evidence which might strengthen the theory that acid metabolites play a part in the local adjustment of blood-flow.

We have also been unable to find that lactic acid exerts any specific influence. The increase in blood-flow which took place during the contractions preceded the rise in the lactic-acid concentration of the venous blood. Further, the lactic-acid level reached its peak some time after the cessation of stimulation, yet this did not produce any further increase in blood-flow. In a different way Domini and Rein (1943) have ascribed to lactic acid a specific effect on the blood-flow. They suggest that lactic acid acts locally by sensitising the blood-vessels to those physiological vasodilator stimuli which are responsible also for the regulation and adjustment of

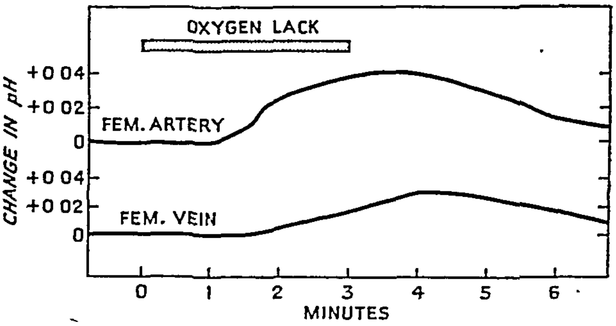

Fig. 11—Effect of oxygen lack in inspired air on pH changes in arterial and venous blood, showing maximal alkaline shift in pH of arterial blood of 0 04 and in venous blood of 0 03.

blood-flow in resting muscle. This hypothesis is of great interest and might possibly explain some of the phenomena of the adjustment of local blood-flow.

Of the known vasodilator substances, acetylcholine, adenosine triphosphate, and histamine have to be considered as being involved in the muscular vasodilatation. *Acetylcholine* may exert an important influence on the muscular blood-flow. When it is released at the motor end-plates its effect may not be limited to these structures; it may also locally dilate the muscle vessels. In our experiments on the dog's muscle acetylcholine may have been released from another source. Bülbring and Burn (1935) have shown that the vessels of the limb muscles in dogs are supplied by sympathetic cholinergic vasodilator fibres, and stimulation of these has not been excluded in our experiments. *Adenosine triphosphate*, the breakdown of which is regarded as the first chemical reaction in muscular contraction, has been considered by Fleisch as a possible vasodilator of the contracting muscle. Up to now, however, there has been no experimental evidence of an increased level of this substance in the venous blood leaving a muscle during or after contraction. Finally, there is *histamine*, the concentration of which has been shown by Anrep and Barsoum (1935) to be higher in the venous than in the arterial blood during muscular contractions. Such a finding suggests that the histamine released from working muscle has a function in the local regulation of blood-flow during muscular activity.

RELATION BETWEEN pH CHANGES IN BLOOD AND CHEMICAL PROCESSES DURING MUSCULAR CONTRACTION

This question cannot be dealt with without referring to the excellent studies of Dubuisson on the isolated frog muscle. The three phases in blood pH which were found in our experiments in the venous blood as a result of isotonic muscular contractions were observed also by Dubuisson (1947) in the isolated sartorius muscle of the frog. He registered continuously by a photographic method the pH changes in the fluid film surrounding the isotonically contracting muscle. As in our experiments, there was an initial phase of acidity followed by alkalinity and finally by prolonged acidity. Dubuisson correlated these changes with (1) the shifting of the iso-electric point of myosin, (2) the breakdown of adenosine triphosphate, (3) the breakdown of creatine phosphate, and (4) the breakdown of glycogen with the formation of lactic acid.

The chemical changes of muscular contractions are so complex that one feels reluctant at this stage of our knowledge to make any definite statement concerning their relation to the pH changes; nevertheless, Dubuisson's work and interpretation deserve careful consideration. On the other hand, the pH changes which we observed in the venous blood of resting muscle under

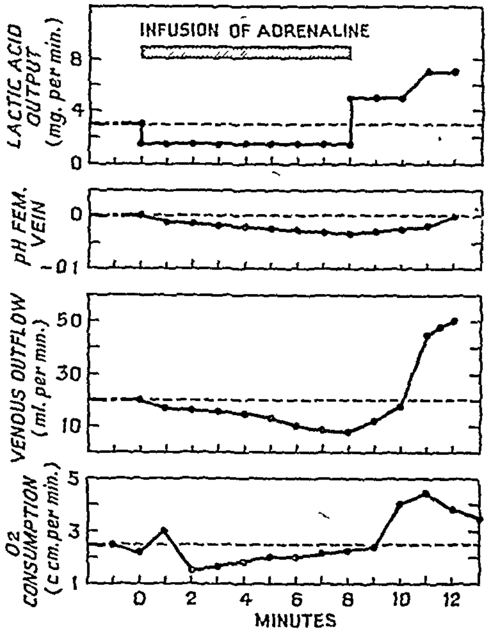

Fig. 8—Effect of adrenaline infusion (0·9 µg. per min.) into femoral artery on: (1) output of lactic acid; (2) pH changes in venous blood; (3) venous outflow; and (4) oxygen consumption of gastrocnemius muscle.

Adrenaline

During a slow infusion of adrenaline into the artery of a resting gastrocnemius muscle the blood in the femoral vein becomes gradually more and more acid. The effect is obtainable with an arterial infusion of 1 µg. of adrenaline per minute (fig. 8). When the adrenaline infusion is discontinued, the acidity persists for a few minutes before the pH gradually returns to normal.

During the infusion of adrenaline the concentration of lactic acid in the venous blood increases slightly, while the output from the muscle decreases by 10–15%; but after the infusion the output of lactic acid increases by as much as 90–290%. The discrepancy between the concentration and the output of lactic acid during the infusion is explained by the changes in muscular blood-flow. The arteries in the resting muscle become constricted during the infusion, and the blood-flow decreases by 50% or even 70%; but afterwards there is considerable hyperæmia. These effects are illustrated in fig. 8, which also shows that the consumption of oxygen follows the blood-flow. Thus during adrenaline infusion an oxygen debt is contracted which is repaid afterwards.

Acetylcholine

When the effects of arterial injections of acetylcholine on the blood pH and oxygen consumption of a muscle are examined, a distinction has to be made between those effects which are the result of muscular contraction and those which are independent of it (Gollwitzer-Meier 1947). With a "closed arterial injection" acetylcholine causes a short twitch-like contraction (Dale et al. 1936), which was shown by Fenn (1941) to be associated with increased oxidation. In our experiments the technical arrangements required for measuring the pH made a "closed arterial injection" impossible. The acetylcholine was either slowly infused in small concentrations for several minutes or injected in a single dose into the femoral artery without special precautions.

In the experiment shown in fig. 9, 2·2 µg. of acetylcholine per minute was infused for 6 minutes. There was a slight muscular effect at the start of the infusion. The blood pH showed an initial shift to the acid side, followed by a strong and persistent alkalinity. The blood-flow increased at the same time, whereas the oxygen consumption decreased by about 50% and remained low during the whole time of infusion. This long-lasting reduction in oxygen consumption suggests that acetylcholine spares the basal metabolism of the muscle. In the experiment shown in fig. 10 a single arterial injection of 5 µg. of acetylcholine was given. A sharp contraction ensued, and at the same time the muscular blood showed the initial shift towards acidity. The contraction was over before the blood became alkaline. The alkalinity coincided again with a lowering of oxidation. Though we have yet no definite proof that the initial acidity is brought about with the muscular contraction, the following observation supports this conclusion. When arterial injections of acetylcholine are repeated, the muscular contractions become smaller and smaller and finally disappear (Brown 1937). We have noted a similar reduction and final disappearance of the initial shift to the acid side on repeated arterial injections of acetylcholine.

Oxygen Lack

During oxygen lack, produced by breathing air with diminished oxygen pressure, the venous blood leaving a resting muscle becomes more alkaline, but the pH of the arterial blood, as is well known, also increases (fig. 11)—more, in fact, than that of the venous blood (Gollwitzer-Meier 1942). This reduction in the arterio-venous pH difference is explained by our finding that the level of lactic acid rises more in the venous than in the arterial blood. There is also an increase in the blood-flow through the muscle of about 50% during oxygen lack, and a further even greater increase when the breathing of normal air is resumed. This hyperæmic after-effect facilitates the repayment of the oxygen debt contracted during the oxygen lack.

Passive Stretching of Muscle

We found that passive stretching makes the venous blood leaving the inactive muscle more alkaline. By this finding Dubuisson's (1947) important discovery that passively stretched isolated frog muscle becomes more alkaline is extended to dog muscle in situ.

MECHANISM OF VASODILATATION DURING MUSCULAR ACTIVITY

It has been assumed for many decades that acid metabolites originating in the active muscle are the cause of the vasodilatation occurring in the muscle during and after its contraction. This conception was challenged to some extent by the results obtained by Fleisch and Sibul (1933) and Fleisch (1938), who perfused the hind legs of a dog with blood containing increasing amounts of carbon dioxide, and found that an increase in hydrogen concentration augmented the blood-flow not more than 100%. In other words, the vasodilatation

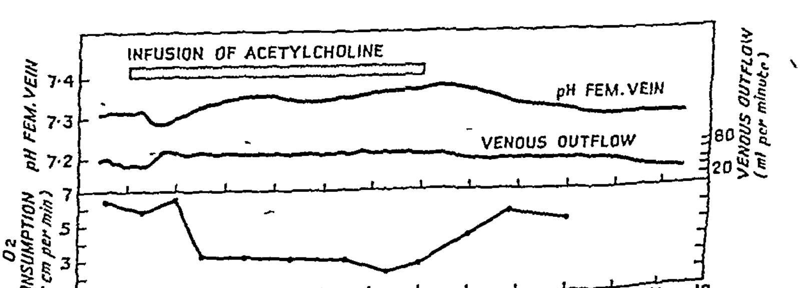

Fig. 9—Effect of infusion of acetylcholine (2·2 µg. per min.) into femoral artery on blood pH, venous outflow, and oxygen consumption of gastrocnemius muscle.

fully. She has been well since, and a further bronchogram, taken five years after the first, showed that there was no bronchiectasis in the re-expanded lower lobe (figs. 4 and 5).

Case B.—A boy, aged 10 months, also a tuberculosis contact with a positive Mantoux test and positive gastric lavage, showed collapse of the right upper lobe. Bronchoscopy on Dec. 17, 1940, showed a narrowed right main bronchus. The collapse persisted but varied in degree from time to time. Bronchoscopy on Feb. 4, 1942, showed a smooth stenosis of the right upper-lobe bronchus. Bronchography of the collapsed area showed crowding of the bronchi and no dilatation. Five years later an X-ray film showed what appeared to be bronchiectasis at the extreme apex of the right lung. This was not confirmed by bronchography, because the parents refused consent. The child has remained symptomless.

These 2 cases seem to indicate that collapse in itself is insufficient to cause bronchiectasis, since in each case bronchography done while the collapse was present showed crowding of the bronchi but no dilatation.

EFFECT OF INCREASED NEGATIVE PRESSURE

Our next step was to measure the intrapleural pressure on both sides in cases of pulmonary collapse.

Technique.—General anæsthesia was induced, usually with gas, oxygen, and ether through an intratracheal tube. Care was taken to be certain that the Magill's tube was in the trachea well above the carina, because early observations showed that inaccurate pressures were obtained if the tube projected into either main bronchus. When the breathing was steady and regular, the intrapleural pressure was measured in the anterior axillary line at corresponding positions on the two sides, with the child on its back. A water manometer was used with the shortest possible piece of rubber tubing connecting it to the Saugmann needle, so as to avoid both lag in manometric swing and introduction of air into the pleural space. There was no discrimination as to which side was investigated first, and the pressures were confirmed by the anæsthetist to avoid any personal bias. When bronchoscopy was performed it was done after the measurement of intrapleural pressures and after chloroform had been substituted for ether. There were no complications. The results are summarised in the accompanying table.

Where the pleuræ were free, as was found in practically all the cases, there was usually no appreciable difference in the pressures. We suggest that, in segmental collapse with free pleura and with the compensatory mechanisms present in the chests of children, the negative intrapleural pressure plays no significant part in the production of bronchiectasis.

In cases A and B, in which collapse persisted for many months, when eventually the bronchial obstruction was relieved, presumably by shrinkage of the gland obstructing the bronchus, oil entered the still collapsed area and the bronchi were seen to be crowded together but not dilated. This finding further supports the view that pull on the bronchi from the pleura plays little part in causing bronchiectasis. In case 11 (see table), where the right upper lobe was collapsed for about five months (fig. 6) and the pleural pressures were virtually equal on the two sides (right − 4 to − 26 mm. ; left − 28 to + 2 mm.), bronchoscopy showed that the right upper lobe was obstructed by caseous material, which was sucked out. The lobe re-expanded (fig. 7), and subsequent bronchography showed no bronchiectasis (fig. 8).

INTRAPLEURAL PRESSURES IN PULMONARY COLLAPSE

Case no.	Situation of collapse	Pleural pressures (mm. of water)		Occurrence of bronchiectasis	Remarks
		Right	Left		
1	Left upper zone	−3, −7	−3, −7	Yes	. .
2	Right upper lobe	−6, +4	−6, +4	Yes	. .
3	Left upper lobe	−5, −10	−4, +2	Yes	Pressures less negative on affected side
4	Left upper lobe	−6, +2	No swing	Yes	Previous left pleural effusion
5	Left upper and middle zones	−4, −2	−10, −2	Yes	.
6	Left upper zone	0, −14	−18, +6	Yes	. .
7	Right upper lobe	−8, −12	−4, −8	Yes	. .
8	Left upper lobe and, later, whole lung	0, −11	0, −8	Yes	. .
9	Left upper lobe	−5, −10	No swing	Yes	Previous left pleurisy
10	Right middle zone	−7, −10	−5, −10	No	. .
11	Right upper zone	−4, −26	−28, +2	No	. .
12	Right middle lobe	0, −5	0, −5	Yes	. .
13	Right middle lobe	−2, −6	−2, −6	Yes	. .
14	Right upper lobe	−2, +2	−2, +2	No	Pressures atypical ; shallow breathing
15	Right upper lobe	0, −10	0, −10	No	. .

OTHER FACTORS

It was observed that in some of the children with primary lesions and pulmonary collapse the collapse persisted for many months without bronchiectasis developing. It was difficult to explain why irreversible bronchiectasis developed in some cases but not in all, and many factors seemed to be concerned.

Distension of Bronchi

The bronchi beyond the block are over-distended and stretched by the retained secretions—mucus, caseous tuberculous material, or pus. This has been found on bronchoscopy in the present investigation, the nature of the retained secretion being determined by sucking up a sample through a catheter passed down the bronchoscope and manœuvred beyond the obstruction. If these secretions can be largely removed by suction or by spontaneous expectoration, the distended bronchi may recover completely and no bronchiectasis will result.

Loss of Elasticity of Bronchial Wall

The spread of tuberculosis to the bronchial wall would interfere with its elasticity ; this risk is increased by the presence of an active primary focus in the collapsed lobe. In the cases bronchoscoped hyperæmia and œdema of the bronchial wall have been seen many times. Gross hyperæmia and œdema causing complete obstruction were seen in 2 cases, and partial obstruction by this means in several cases. In 1 case the grossly affected mucosa was thrown into folds and caused complete collapse of the right middle lobe for sixteen months.

In case 8 (see table) glandular swelling, with overlying œdema, caused complete obstruction of the left main bronchus, associated with pyrexia and severe malaise. The obstruction was relieved by passing a gum-elastic catheter and sucking up the infected secretions from beyond the block. The lumen was re-established by passing a gum-elastic catheter repeatedly until the danger of complete obstruction recurring had passed. Twelve months later a granulomatous polyp was seen projecting into the right main bronchus. Two years later an irregularity of the margin of the orifice of the left upper-lobe bronchus and a little generalised narrowing of the left main bronchus were found. Bronchography showed bronchiectasis in the left upper lobe, but the remainder of the lung, despite the previous collapse, was normal (figs. 9–11).

In 8 other cases granulomatous polypi were seen projecting into the lumen of the bronchi and causing complete or partial obstruction. Caseous ulceration was seen in 4 cases. In 1 case the pedunculated polyp was sucked off, leaving a bleeding area at the site of attachment and a thickened swollen mucosa throughout the remainder of the bronchus. This polyp showed calcification and tubercles but no giant cells. Obstruction was present in this case for fifteen months. These large polypoid masses have been seen to persist, gradually getting smaller, for sixteen months, for it was the practice to repeat bronchoscopy on these patients at intervals of three to six months.

If these gross findings are seen in the main bronchi, it is reasonable to suppose that in some cases the bronchi outside bronchoscopic range may become involved in a tuberculous lesion, either directly or by ulceration of various conditions show how difficult it is to associate such changes with chemical processes of muscular activity, and how cautious one must be in trying to generalise and to correlate pH changes in the blood with definite processes of muscular metabolism.

With illustrations on plate

A GREAT deal has been written on the possible causative factors in bronchiectasis. Andral, writing in 1824, mentioned that, especially in children, the bronchi are sometimes distended by accumulated mucus, and their walls may then yield. Stokes, of Dublin, in 1837, suggested that in most cases bronchial dilatation occurs when a bronchial wall has been weakened by inflammation or by loss of its muscular tone, so that it yields to forces, such as violent cough, which it would otherwise withstand. He also believed that interference with ciliary movement plays an important part in the ætiology. Hughes and Simpson (1940) discussed the rôle of enlarged glands and granulation tissue. They thought that tuberculous hilar glands may interfere with respiration in various ways: (1) a gland may narrow or completely occlude a bronchus by external compression; (2) an abscess in a gland may point through a bronchial wall and rupture into the bronchus, asphyxiating the child; and (3) a mass of granulation tissue in the bronchial wall may obstruct a bronchus. With any of these conditions the additional factor of thick viscid purulent obstructive secretions may co-exist. Hughes and Simpson stated, however, that these conditions are comparatively rare.

Meneghello and Smith (1943) reported on 15 infants and children in whom tuberculosis caused mechanical obstruction of the bronchial passages, and they indicated that the tuberculosis may produce either pulmonary collapse or emphysema; that younger children were more often affected than older children; and that, though collapse and emphysema may persist for six months or more, complete recovery is the rule. In their follow-up they found only 1 case out of 7 in which long-standing collapse of the lobe led to evidence of bronchiectasis.

Brock et al. (1937) described the anatomy of the bronchial glands and suggested that the secondary changes in the lung are due to simple collapse following bronchial obstruction from the pressure of enlarged caseous lymph-glands. They stated that no proved case has been followed into adolescence and adult life and bronchiectasis demonstrated clinically and radiologically.

Lee Lander and Davidson (1938) focused attention on pulmonary collapse and bronchiectasis and, from experimental evidence in cats, advanced the theory that the bronchi in the collapsed area are subjected to pull because of the increased negative intrapleural pressure. They obstructed the bronchi with mucin.

Jennings (1937) reported a case in which bronchiectasis occurred in a collapsed lobe and then disappeared with re-expansion.

PRESENT INVESTIGATION

During the war years 421 children were inpatients at Harefield Hospital, and it was decided to investigate the incidence of pulmonary collapse and the incidence and ætiology of bronchiectasis in this group. There were 400 cases of primary lung lesions, of which 77 (19%) showed collapse of a segment, a lobe, or a lung. Owing to war-time difficulties not all of these 77 cases were fully investigated, but bronchography was done in 37, bronchiectasis being found by this means in 34. In addition, 12 cases showed obvious bronchiectasis on plain radiography, bringing the total to 46 (60%). Cases were followed for periods up to seven years. There were 31 cases of pulmonary collapse in which the most careful clinical and radiological scrutiny did not reveal any suggestion of bronchiectasis.

The anatomical distribution was as follows:

Pulmonary collapse with bronchiectasis	
Right upper lobe	17
Right middle lobe	5
Right lower lobe	2
Combined (R.M.L. and R.L.L.)	4
Total	28 right
Left upper lobe	15
Left lower lobe	2
Total	17 left
Both sides (R.L.L. and L.U.L.)	1
Pulmonary collapse without bronchiectasis	
Right upper lobe	8
Right middle lobe	7
Right lower lobe	6
Total	21 right
Left upper lobe	4
Lingula	1
Left lower lobe	2
Combined (L.L.L. and lingula)	2
Whole left lung	1
Total	10 left

EFFECT OF COLLAPSE ALONE

It seemed reasonable to suppose that uncomplicated mechanical pulmonary collapse should produce crowding and not dilatation of the bronchi unless increased negative intrapleural pressure is sufficient, as Lee Lander and Davidson (1938) suggested, to dilate the bronchi. This aspect was investigated first.

Case A.—A girl, aged 8 months, had a localised emphysema of the right lower lobe due to partial obstruction, probably by a gland (fig. 1). There was no doubt about the tuberculous ætiology, for she was a tuberculosis contact, her Mantoux test was strongly positive, and tubercle bacilli were grown after gastric lavage. The presenting symptom was continuous asthma, thought to be due to reflex bronchial spasm from vagal stimulation in the over-distended right lower lobe. This was followed by collapse of this lobe and cessation of the asthma. Bronchoscopy while the collapse was present showed no intrabronchial lesion. Bronchography showed crowding of bronchi in the collapsed lower lobe (figs. 2 and 3). It was concluded that the obstruction was probably due to glandular pressure which had subsided, and that, though alveolar collapse persisted, there was no bronchiectasis. The lobe remained collapsed for about a year and then re-expanded. The infant remained free from symptoms for three years and then had pneumonia, from which she recovered unevent-

STREPTOMYCIN AND THE PRIMARY LUNG LESION IN TUBERCULOSIS IN CHILDREN

JOHN LORBER
M.B. Camb., M.R.C.P., D.A.
RESEARCH ASSISTANT, DEPARTMENT OF CHILD HEALTH, UNIVERSITY OF SHEFFIELD

With illustrations on plate

IN this country the use of streptomycin in tuberculosis of children has been confined almost entirely to the treatment of miliary or meningeal disease. Many feel that it should be used for the treatment of primary tuberculosis in an attempt to cure the disease and to prevent miliary or meningeal spread.

Now that streptomycin has been released for general use, it is opportune to examine the evidence for and against its use in primary pulmonary tuberculosis. Children with uncomplicated primary lesions have been treated abroad, but without controls and with an insufficient follow-up period. It is generally agreed that, though there may be symptomatic improvement, the large parenchymal or hilar foci are little influenced by streptomycin (Sanford and O'Brien 1947, Fanconi and Dolivo 1948, Lamy et al. 1948, Löffler and Piotti 1948, Mouriquand et al. 1948, Wissler 1948, McEnery et al. 1949, Morin 1949).

Several writers, describing the effect of streptomycin on miliary and meningeal tuberculosis, have noted that the primary lung complex did not respond to treatment either from the clinical or the pathological point of view (Baggenstoss et al. 1947, McDermott et al. 1947, Dubois et al. 1948, Flory et al. 1948, Medical Research Council 1948, Montgomery 1948, Zollinger 1948, Rubie and Mohun 1949).

Most of the above observations formed a minor part of papers dealing mainly with other subjects. It was therefore decided to investigate a series of cases treated in Sheffield to determine the effect of streptomycin on the primary lung lesion.

MATERIAL

Over 90 tuberculous children have been treated with streptomycin, mostly for miliary and meningeal dissemination. Only those 22 cases which satisfied all the following criteria were included in this study:

(1) Part or whole of a large primary tuberculous complex was clearly demonstrated in chest radiograms just before or immediately after the start of treatment.

(2) The tuberculous nature of these lesions was established beyond doubt by the presence of a positive tuberculin reaction in all the patients, and by positive cultures from gastric washings or by coexistent miliary or meningeal tuberculosis.

(3) A minimum of three months' streptomycin treatment was given.

(4) Survival permitting, a minimum of six months elapsed after the start of the treatment.

(5) Autopsy was performed in all children who died.

In association with the primary tuberculous complex 5 children had meningitis, 7 miliary tuberculosis and meningitis, and 8 miliary tuberculosis; 2 had uncomplicated tracheobronchial primary tuberculosis. The age on admission ranged from 9 months to $7^1/_2$ years; 15 children were under the age of 2 years.

TREATMENT

Intramuscular streptomycin was given usually in doses of 20 mg. per lb. of body-weight daily, but 6 children had larger doses for part of the time. The treatment was continuous in 20 children. Rest periods were given in 1 case because of an unusually protracted course, and in 1 other case because of toxic erythema. In 4 of the continuously treated children further courses had to be given because of relapse of the meningitis. This scheme of treatment has proved satisfactory in miliary tuberculosis and meningitis; in this series 15 of the 20 children are alive after six to twenty-four months' observation.

The details of age, sex, dosage, duration of treatment, and of observation are given in table I. Table II shows the radiological features.

EFFECT ON SYMPTOMS

Symptoms attributable to the glandular component of the primary complex were present in 6 children: 2 of these had tracheobronchial tuberculosis without miliary spread (cases 9 and 19); 1 child was admitted to hospital because of primary tuberculosis and the miliary spread took place during observation; the remaining 3 children were admitted with miliary tuberculosis already present. The following is a summary of the histories of these 6 cases.

Case 5.—A girl, aged 22 months, was admitted with chronic cough, anorexia, and irritability. She had a large tuberculous primary lesion in her right lung. She improved considerably with rest in bed, gained weight, and was discharged after four months. Two months later she was readmitted because of increase of cough and loss of weight, and a radiogram suggested miliary spread.

A protracted course of streptomycin was given, but eight months later, long after the suspected miliary lesions had disappeared, she still had a cough. The primary lung lesion was still present.

Cases 6 and 7.—Both these children had miliary tuberculosis which cleared on treatment. Case 6, a girl of one year, was left with a cough and stridor due to compression of the left main bronchus by enlarged glands. These symptoms were clearing fourteen months after treatment ended. Case 7, a boy of sixteen months, was similarly left with stridor and dyspnœa on exertion, but these symptoms disappeared five months after the end of treatment.

Case 9.—A girl, aged 10 months, had been wheezing and coughing for seven months but was otherwise well. On admission to hospital she had a severe cough and some stridor. During four and a half months' observation before streptomycin therapy the clinical course was fluctuating. There was steady improvement for three months, but the patient relapsed and had cough and stridor for the next six weeks. As a result of a particularly severe attack of stridor and dyspnœa streptomycin was started. The patient improved for six weeks but had another relapse with dyspnœa and cyanosis. A remission was followed by a third relapse. Cough persisted at the end of four and a half months' treatment, but subsequently the patient made a good clinical recovery.

Radiologically a tuberculous focus in the right upper lobe and a mass of paratracheal glands showed steady slow improvement which was not hastened by streptomycin treatment. The chest was not quite clear a year after admission.

Case 18.—A boy, aged 18 months, had had a cough for a year and loss of appetite for four or five months. He was admitted with miliary tuberculosis and right hilar flare (fig. 3). The miliary tuberculosis was cured, but after six months cough and wheezing on exertion persisted and the radiogram showed segmental consolidation of the right middle and lower lobes. After nearly nine months' treatment the cough was severe even at rest. Radiography showed no improvement (fig. 3a).

Case 19.—A boy, aged 14 months, had suffered from wheezing for five weeks and cough for three or four weeks. On admission he had well-marked expiratory stridor but was not very ill. Four days later he suddenly became severely dyspnœic, cyanosed, and semiconscious, and his stridor increased. The cerebrospinal fluid was normal. Spontaneous improvement was evident within a few hours. Streptomycin was started and was given for three months. There was progressive improvement, though the patient still had a slight cough at the end of treatment and six months later.

Radiologically the right upper lobe and paratracheal lesions were worse at the end of treatment than at the beginning, in spite of some initial improvement.

It may be concluded that in these 6 cases there is no clear evidence that streptomycin affected the symptoms extrinsic disease into the bronchi. These factors would obviously reduce the elasticity of the bronchial wall and prevent its recovery, particularly if the bronchi were subjected to distension by frank caseous material or retained mucus. Provided these distended bronchi are not subjected to secondary infection, some recovery may be anticipated, and a striking absence of symptoms is found.

Inflammation of Bronchi

The bronchial wall, if the bronchus is distended with pus, will soon become involved in the inflammatory process and further weakened. If the obstruction is unrelieved, the inflammation may involve the surrounding lung tissue and further irreparable damage may be done. Case 2 (see table) illustrates this point. At the height of this boy's illness his clinical state and physical signs were those of pneumonia of the right upper lobe (fig. 12). A mistake was made in not appreciating the true condition—i.e., retention of pus beyond the bronchus blocked by tuberculous inflammation. The patient showed little response to chemotherapy. Bronchoscopy relieved the symptoms, but unfortunately by this time irreparable damage had been done, and the end-result was a shrunken bronchiectatic upper lobe (fig. 13).

SYMPTOMS AND TREATMENT

As would be expected from mechanical considerations, symptoms tend to arise when bronchiectasis is situated in the lower part of the lungs, where spontaneous drainage is more difficult. That the bronchial dilatation may persist for many years without symptoms is borne out by the cases which we have followed up for periods up to seven years (31 out of 42 cases symptomless). The patients may, however, have a hæmoptysis even after many years (2 out of the 42 cases had hæmoptysis after one and a half and seven years). The following 2 cases in adults further illustrate this point.

Case C (figs. 14 and 15).—In this patient there is gross cystic bronchial dilatation in the right upper lobe, with a calcified gland at the root; the only symptom was hæmoptysis at the age of 36.

Case D (fig. 16).—This patient, aged 25, who has obvious disseminated calcified lesions in the lungs, also presented with hæmoptysis, and was found to have bronchial dilatation in a collapsed left lower lobe, an obvious relic of primary infection in childhood.

Secondary Infection

Constitutional disturbances may arise if the bronchiectatic areas become infected, which is likely to happen in children either from a downward spread of an upper respiratory infection or as a complication of measles or whooping-cough. An upper-lobe dilatation is less likely to cause symptoms, because of the mechanical drainage owing to its position. On the other hand, the bronchi in the more dependent parts of the lungs will tend to become infected and secretions to be retained whenever the patient contracts an infection (such as measles and whooping-cough complicated by bronchitis), unless the bronchi are kept clear by postural drainage. The rôle of secondary infection seems to be of paramount importance, particularly if some obstruction is present.

It has been observed in our cases that a primary lesion with segmental collapse may cause little or no symptoms; but, if secondary organisms penetrate beyond the obstruction, the retained mucopus will cause further distension and damage to the bronchial wall. Toxic absorption may then occur; an event which is indicated clinically by pyrexia. As a rule the fever shows little response to chemotherapy. This is an indication for immediate bronchoscopy with the passage of a gum-elastic catheter beyond the block and suction. This has been done in some of our cases from time to time with dramatic results. Where basal collapse exists it is a wise precaution to use postural drainage of the affected area, even if there is no sputum. When the obstruction is relieved by the shrinkage of a gland, or by the coughing up or resolution of a polypoid mass, the retained secretions are expectorated and secondary infection with retention minimised. Any intercurrent infection in children with primary lesions associated with collapse demands prompt and energetic treatment to prevent or minimise permanent damage to the bronchi and lungs.

There is another important point about childhood bronchiectasis following a primary tuberculous lesion. If bronchoscopy shows an active bronchial lesion, or pressure by an enlarged gland is diagnosed, two years or more should be allowed to elapse after resolution, before lobectomy, if indicated, is undertaken. Further, the operation should be covered with streptomycin. A short course of streptomycin has also been used in a few cases where the bronchial involvement seemed to be severe.

SUMMARY

Primary tuberculous lesions associated with pulmonary collapse are followed in an appreciable proportion of cases by bronchiectasis, which is often symptomless.

Involvement of the bronchi by a tuberculous lesion, whether through extrinsic pressure from a gland, œdema of the bronchial mucosa, or infiltration of the bronchial wall, may lead to distension of the bronchi beyond the obstruction by retained mucus, tuberculous caseous material, or by secondary infection of the retained mucus. This distension is an important factor in producing bronchiectasis. Symptoms commonly arise when secondary infection intervenes.

Increased negative intrapleural pressure causing a pull on the bronchi in localised pulmonary collapse where the pleura is free seems to be of negligible significance in the causation of bronchiectasis.

In children with pulmonary collapse a Mantoux test should be done and, if it is positive, possible sources of tuberculous infection should be sought.

Bronchoscopy for diagnosis, combined with suction and postural drainage, is advised both for prophylaxis and treatment, and should be undertaken immediately if there is evidence of secondary infection beyond the block.

If an operation is indicated for bronchiectasis in a child, a tuberculosis aetiology should always be considered, and, if it is found, at least two years should be allowed for the tuberculous lesion to heal before operation is undertaken, and streptomycin should be used to cover the operation.

In view of the rôle of secondary infections in producing symptoms and irreversible changes in the bronchi and lung, these infections should be treated energetically. Particular attention should be paid to the upper respiratory tract as a potent source of infection of the collapsed area.

We wish to thank Dr. I. Parry Brown for his skill in anæsthetics, making the investigation possible and free from complications, and for his helpful criticism; Mr. A. W. Holder and the staff of the X-ray department for their technical assistance; Sister Creed, department sister of the children's unit, for her coöperation; Dr. Mary Tate for assistance with the analysis of the cases; and Dr. K. R. Stokes, medical director, Harefield Hospital, for encouragement and discussion.

TABLE II—RADIOLOGICAL DETAILS OF THE PRIMARY LESIONS

Group	Case no.	Part of lung involved	Course during treatment	Radiological appearances	
				At end of treatment	On Sept. 30, 1949
1 (gradual improvement)	1	R.L.L., R. hilum	Slow improvement	Improved	Clear
	2	L.L.L.	Slow improvement	Improved	Clear
	6	L.U.L., L.L.L., L. hilum	Slow improvement (calcifying)	Improved	Still large opacity and mass of calcification
	9	R.U.L., R. paratracheal	Slow improvement	Improved	Focus in R.U.L. and glands calcifying
	13	R.U.L., R. hilum	Slow improvement	(Died)	..
	20	R. paratracheal	No change, followed by slow improvement	Improved	Clear
	21	R. hilum and paratracheal	No change, followed by slow improvement	Slightly improved	Glands still enlarged
2 (fluctuating course)	3	R.U.L.	Getting worse for 2 mos., then improving	Improved	Faint fibrosis R.U.L.
	5	R.M.L., R. hilum	Fluctuating course, but getting worse for 7 mos.; new lesion L.U.L.	Worse	R.M.L. collapse; mass of left paratracheal glands
	10	R.U.L. and R.M.L., R. paratracheal	Getting worse for 5 mos., then slow improvement	Worse	R.M.L. collapse
	11	Normal	Primary complex appeared in L.U.L. and L. hilum, followed by improvement	Worse	Clear
	12	L. hilum	L.U.L. collapsed and partly cleared again	(Died)	..
	16	R. hilum	Lesion extending into R.U.L., later clearing	Still being treated	R. paratracheal glands calcifying
	19	R.U.L., R. paratracheal	Initial improvement followed by marked relapse	Worse	Clear
3 (no change)	4	R. hilum	No change	Same	Clear
	7*	R. lung, R. hilum	No change	Same*	Slightly smaller mass
	15	L. hilum	No change	(Died)	..
	22	L. hilum	No change	(Died)	..
4 (progressive deterioration)	8	L.U.L.	See text	Worse	Incipient calcification
	14	R. hilum	Progressively bigger, extending into R.U.L.	(Died)	..
	17	L. paratracheal	Progressively bigger	Worse	Almost normal
	18*	R.L.L., R.M.L., R. hilum	Much increasing in size and density	Worse*	Still very large lesion

* Again treated for meningeal relapse. R.U.L., R.M.L., R.L.L., right upper, middle, lower lobe. L.U.L., L.L.L., left upper, lower lobe.

sulated, being multiple in case 13. In the 2 others they were small and encapsulated. The regional glands were also caseous in all 5 children, and particularly large in case 14. Segmental collapse of a lobe was present in cases 12 and 13, and in case 12 this was associated with tubular bronchiectasis. There seemed to be no difference between these lesions and those found in untreated cases.

TOXIC EFFECTS

Toxic effects persisted after the end of treatment only in case 8; this girl is now totally deaf. A transient toxic erythema developed in 4 children.

DISCUSSION

This study cannot be taken to show the effect of streptomycin on uncomplicated primary pulmonary tuberculosis in childhood; only 2 of the children fall into this category, all the others having miliary or meningeal tuberculosis in addition. Conclusions therefore must be guarded. Even so, the findings indicate the course of the clinical, radiological, bacteriological, and pathological response of the primary pulmonary lesion during and after protracted treatment with streptomycin given in adequate doses. The number of cases is small, but the results were uniform. There were no controls, because of the special nature of the cases treated. It is clear, however, that in these cases streptomycin had little or no effect on the primary complex or on the excretion of tubercle bacilli even after protracted treatment.

There is no evidence that streptomycin will prevent miliary tuberculosis when given for the treatment of primary tuberculosis. There does not seem, however, to be any certain record of miliary tuberculosis developing when uncomplicated meningitis was treated with streptomycin. There is good evidence that in miliary tuberculosis streptomycin treatment will not prevent the development of meningitis. In 21 children admitted and treated for uncomplicated miliary tuberculosis, meningitis developed during treatment in 10 (unpublished results). Streptomycin is toxic and may cause permanent deafness, and the tubercle bacillus may become resistant to it.

The good prognosis of primary tuberculosis in children over the age of 3 years is well known (Wallgren 1941, Brailey 1943, Levine 1944). The prognosis is worse in infants and children under this age, but Mitchell and Willis (1944) have shown that even in this group the case-mortality can be reduced to 9% by conservative management. Death is usually due to meningitis and miliary tuberculosis. These figures were obtained before the days of streptomycin treatment of miliary tuberculosis and meningitis and could probably be considerably bettered today, in view of the good response of many cases of meningitis and most cases of miliary tuberculosis.

In conclusion, these results suggest that it is unwise and possibly dangerous to give streptomycin for uncomplicated cases of primary tuberculosis. Protracted experiment with proper controls is required to confirm or disprove this suggestion.

SUMMARY

The effect of streptomycin on the primary complex in the lung in 20 children with miliary tuberculosis and meningitis and 2 children with tracheobronchial tuberculosis is described.

It was not possible to demonstrate any beneficial effect of streptomycin on the primary complex or the symptoms attributed to it.

In 8 cases tubercle bacilli persisted in stomach washings for over six months after treatment had started.

On the present evidence it seems unwise to treat uncomplicated primary tuberculosis with streptomycin.

This study was carried out under the streptomycin investigation scheme of the Ministry of Health.

My thanks are due to Prof. R. S. Illingworth, under whose care most of the patients were treated, for his help and criticisms; Dr. T. Colver and Dr. R. Gordon for permission to investigate their patients; Dr. J. L. Emery, who performed all the autopsies; Dr. T. Lodge for the radiographs; Miss S. Stewart for her bacteriological work; and Sir Weldon Dalrymple-Champneys for permission to publish.

due to the primary lesions. The course of all cases corresponded with what could be expected from rest in bed alone.

EFFECT ON RADIOLOGICAL CHANGES

The response of the 22 cases during treatment, as seen radiologically, can be classified as follows:

Group 1:	progressive slow improvement	7 cases
Group 2:	fluctuating course during treatment ..	7 ,,
Group 3:	*no appreciable change*	4 ,,
Group 4:	progressive deterioration	4 ,,

These cases are listed in table II, but some of the radiological changes are described in greater detail below (see also figs. 2 and 2a).

Case 6.—This girl presented with an extensive opacity in the left lung (fig. 1). After four months' treatment this was appreciably smaller and calcification had appeared in the left upper lobe. The improvement continued and the calcification increased for the next six months. Then, however, a left-sided pleural effusion developed as evidence of continued activity of the disease, together with further positive gastric washings. The fluid was absorbed, but nineteen months after the original film was taken there was still a considerable opacity in the left lung, with glandular enlargement, displacement of the trachea to the right, and a large calcified mass in the upper lobe (fig. 1a).

Case 8.—The original film of this girl, aged 16 months, showed a massive coarse miliary picture, partly hiding the primary focus in the left upper lobe. In fifty days the bases cleared, leaving opacities at both apices, with a cavity on the right side. A month later a left-sided spontaneous pneumothorax developed. The apex of the lung contained at least one cavity which was held out by a thick adhesion to the chest wall. The pneumothorax resolved in a month. Cavities were present in both upper lobes, and at the right apex obstructive emphysema was present which increased in size for a month, but disappeared later. Six months after the beginning of treatment the films were typical of bilateral fibrocavernous tuberculosis of the adult type. Improvement then occurred, but after more than a year's treatment and seventeen months' observation the patient still has chronic apical lesions, though cavities are no longer evident and calcification is beginning to show.

Case 12.—This girl, aged 17 months on admission, died. At the beginning of treatment for meningitis she had merely a left mediastinal lymph-node enlargement, but this led to massive collapse of the left upper lobe four months later. This collapse had largely cleared before death, but not before it had led to tubular bronchiectasis, which was found at necropsy.

Case 16.—The treatment in this case was unorthodox. The girl, aged 2 years 10 months, was given a massive dose of 60 mg. per lb. of body-weight for two months for her meningitis. During this period there was progressive deterioration in the radiological appearances. A large mass of right paratracheal glands led to collapse of the whole upper lobe. Then she had *no further treatment for nearly five months.* During this time there was considerable fluctuation in the radiological appearances; the lobe became re-aerated only to collapse again later. When streptomycin therapy was started again because of relapse of the meningitis there was but slight enlargement of the glands. During the second course of streptomycin these glands are beginning to calcify.

At the end of September, 1949, 17 of the 22 children were alive. In 6 of them the X-ray films of the chest were clear, and in 3 others healing took place by calcification or fibrosis in a minimum of seven and maximum of twenty months from the beginning of treatment. *In the 8 other survivors lesions of various size, some very large,* were still present six to nineteen months after treatment had started.

There is no evidence on the basis of these findings that streptomycin affected either beneficially or adversely the natural course of the primary complex.

EFFECT ON BACTERIOLOGY AND PATHOLOGY OF PRIMARY TUBERCULOSIS

Positive cultures were obtained during life from the gastric contents of 12 children. All the organisms tested were sensitive to streptomycin before therapy. Positive cultures were repeatedly obtained from 10 of 12 children after treatment had started—in 8 of them for six months or longer. In one child (case 8) the organism became resistant to 1000 μg. of streptomycin after four months. In contrast, no positive cultures could be obtained more than two months after treatment had started in any of our cases of miliary tuberculosis without a radiologically visible primary focus.

Caseous primary foci were found in the lungs in all 5 children who died. In 3 these were large and not encap-

TABLE I—DETAILS OF CASES AND TREATMENT

CYSTIC PULMONARY FIBROSIS IN GENERALISED SCLERODERMA

REPORT OF TWO CASES

R. E. CHURCH
M.A., M.B. Camb.
REGISTRAR, SKIN DEPARTMENT

A. R. P. ELLIS
D.S.O., M.B. Camb.
MEDICAL REGISTRAR

ADDENBROOKE'S HOSPITAL, CAMBRIDGE

With illustrations on plate

THE early symptoms of generalised scleroderma often lead the patient to consult a dermatologist. However, the ramifications of the disease extend more deeply than the skin, since scleroderma is a disease of the connective tissue as a whole. Recently attention has been focused on the internal organs which may also be involved in the sclerotic process (Beerman 1948). Affections of heart, œsophagus and alimentary tract, kidneys, pituitary, thyroid, adrenals, eyes, and larynx have all been described in scleroderma. Pulmonary changes are becoming more widely recognised as they are sought, and it is to these that we are giving our particular attention.

In early descriptions of generalised scleroderma dyspnœa and liability to pulmonary infection were generally attributed to restriction of respiratory movements by sclerotic changes in the skin and muscles of the chest wall, but it seems likely that respiratory symptoms may often have been due to undetected fibrotic changes in the lungs themselves. In 1889 Finlay described the case of a man, aged 36, with generalised sclerosis of the skin, clawing of the hands, and pigmentation. The patient was troubled with chronic cough and dyspnœa. Examination showed impaired movement of the chest with signs of generalised bronchitis and of consolidation at the left base. Two years later Finlay (1891) recognised the association between scleroderma and pulmonary fibrosis. Lewin and Heller (1895) reviewed a large number of published cases of scleroderma, including that of Finlay. In 6 of these cases dyspnœa was conspicuous, and they associated it with sclerosis of the chest wall rather than of the lung. Thickening of the aryteno-epiglottic folds was suggested as a contributory factor. Of their 28 autopsy cases, fibrosis of the lungs was present in at least 2, and emphysema, pleurisy, and tuberculosis were found in others. Matsui (1924) reported 6 cases of scleroderma with post-mortem findings. In 3 of these pulmonary fibrosis was found at autopsy though there had been no symptoms to suggest it during life.

Most of the previous reports on the lung changes in scleroderma have described generalised fibrosis of the lungs particularly affecting the lower lobes, with radiological appearances suggesting bronchiectasis. Linenthal and Talkov (1941) reported 3 cases of pulmonary fibrosis associated with Raynaud's phenomenon, a common presenting feature of scleroderma. X-ray films of the chest in all 3 cases showed exaggerated lung markings, particularly affecting the lower zones, the apices being largely spared. Murphy et al. (1941) described the case of a negress whose chest X-ray film showed a diffuse network of fibrosis throughout both lungs. Bronchography, as in most other reported cases, was normal. Weiss et al. (1943), in their description of 9 cases with heart involvement, found diffuse mottling opacity in the lungs of 6. The appearances suggested lipoid pneumonia or bronchiectasis. Microscopic examination of the lungs from 2 of these cases showed extensive fibrosis and thickening of the alveolar walls with coarse collagenous connective tissue. Peribronchial and perivascular connective tissue was increased in amount, causing diminution in the calibre of both bronchi and blood-vessels. Fox (1947) reported a case of scleroderma of acute onset following "influenza," in which chronic cough and dyspnœa developed and X-ray films showed diffuse pulmonary fibrosis. Bourn (1947) remarked on the presence of lung fibrosis in 2 of his 3 cases of acrosclerosis with œsophageal lesions; in 1 case the fibrosis affected particularly the right apex, whereas in the other it was basal.

Four further cases of generalised scleroderma with diffuse pulmonary fibrosis were recorded by Lloyd and Tonkin (1948). The lung changes were predominantly basal. Three of these cases presented with typical Raynaud attacks. The case of Wigley et al. (1949) is of particular interest since dyspnœa and pulmonary fibrosis preceded the appearance of skin changes by over two years. Other cases showing radiological evidence of pulmonary sclerosis have been reported by Jackman (1943), Kanee (1944), Bevans (1945), Mathison and Palmer (1947), and East and Oram (1947).

None of these writers mentions cystic changes in the lungs in any of their cases. Dostrovsky (1947) however describes 3 cases of progressive scleroderma associated with fibrosis and cyst formation in the lungs, which he called pulmosclerosis cystica. The cases were under his observation for a long time. In the lung he found that much of the lung tissue had been replaced by fibrous tissue containing numerous cavities. In all 3 cases there was no clinical evidence of pulmonary fibrosis for a considerable period after the appearance of skin changes.

With illustrations on plate

THE early symptoms of generalised scleroderma often lead the patient to consult a dermatologist. However, the ramifications of the disease extend more deeply than the skin, since scleroderma is a disease of the connective tissue as a whole. Recently attention has been focused on the internal organs which may also be involved in the sclerotic process (Beerman 1948). Affections of heart, œsophagus and alimentary tract, kidneys, pituitary, thyroid, adrenals, eyes, and larynx have all been described in scleroderma. Pulmonary changes are becoming more widely recognised as they are sought, and it is to these that we are giving our particular attention.

In early descriptions of generalised scleroderma dyspnœa and liability to pulmonary infection were generally attributed to restriction of respiratory movements by sclerotic changes in the skin and muscles of the chest wall, but it seems likely that respiratory symptoms may often have been due to undetected fibrotic changes in the lungs themselves. In 1889 Finlay described the case of a man, aged 36, with generalised sclerosis of the skin, clawing of the hands, and pigmentation. The patient was troubled with chronic cough and dyspnœa. Examination showed impaired movement of the chest with signs of generalised bronchitis and of consolidation at the left base. Two years later Finlay (1891) recognised the association between scleroderma and pulmonary fibrosis. Lewin and Heller (1895) reviewed a large number of published cases of scleroderma, including that of Finlay. In 6 of these cases dyspnœa was conspicuous, and they associated it with sclerosis of the chest wall rather than of the lung. Thickening of the aryteno-epiglottic folds was suggested as a contributory factor. Of their 28 autopsy cases, fibrosis of the lungs was present in at least 2, and emphysema, pleurisy, and tuberculosis were found in others. Matsui (1924) reported 6 cases of scleroderma with post-mortem findings. In 3 of these pulmonary fibrosis was found at autopsy though there had been no symptoms to suggest it during life.

Most of the previous reports on the lung changes in scleroderma have described generalised fibrosis of the lungs particularly affecting the lower lobes, with radiological appearances suggesting bronchiectasis. Linenthal and Talkov (1941) reported 3 cases of pulmonary fibrosis associated with Raynaud's phenomenon, a common presenting feature of scleroderma. X-ray films of the chest in all 3 cases showed exaggerated lung markings, particularly affecting the lower zones, the apices being largely spared. Murphy et al. (1941) described the case of a negress whose chest X-ray film showed a diffuse network of fibrosis throughout both lungs. Bronchography, as in most other reported cases, was normal. Weiss et al. (1943), in their description of 9 cases with heart involvement, found diffuse mottling opacity in the lungs of 6. The appearances suggested lipoid pneumonia or bronchiectasis. Microscopic examination of the lungs from 2 of these cases showed extensive fibrosis and thickening of the alveolar walls with coarse collagenous connective tissue. Peribronchial and perivascular connective tissue was increased in amount, causing diminution in the calibre of both bronchi and blood-vessels. Fox (1947) reported a case of scleroderma of acute onset following "influenza," in which chronic cough and dyspnœa developed and X-ray films showed diffuse pulmonary fibrosis. Bourn (1947) remarked on the presence of lung fibrosis in 2 of his 3 cases of acrosclerosis with œsophageal lesions; in 1 case the fibrosis affected particularly the right apex, whereas in the other it was basal.

Four further cases of generalised scleroderma with diffuse pulmonary fibrosis were recorded by Lloyd and Tonkin (1948). The lung changes were predominantly basal. Three of these cases presented with typical Raynaud attacks. The case of Wigley *et al.* (1949) is of particular interest since dyspnœa and pulmonary fibrosis preceded the appearance of skin changes by over two years. Other cases showing radiological evidence of pulmonary sclerosis have been reported by Jackman (1943), Kanee (1944), Bevans (1945), Mathison and Palmer (1947), and East and Oram (1947).

None of these writers mentions cystic changes in the lungs in any of their cases. Dostrovsky (1947) however describes 3 cases of progressive scleroderma associated with fibrosis and cyst formation in the lungs, which he called pulmosclerosis cystica. The cases were under his observation for a long time. In the lung he found that much of the lung tissue had been replaced by fibrous tissue containing numerous cavities. In all 3 cases there was no clinical evidence of pulmonary fibrosis for a considerable period after the appearance of skin changes.

The histological changes in Dostrovsky's cases are discussed by Getzowa (1945), who suggests that the primary morbid process takes place in the connective tissue, the blood-vessels and lung parenchyma being secondarily affected. The microscopic changes in the lungs were found to be identical with those occurring in the sclerosed skin. This is not in agreement with Baehr and Pollack (1947), who consider that the primary changes of scleroderma are vascular with endarteritis and fibrinoid necrosis of the vessel walls and surrounding collagen tissue. It may be concluded that fibrosis, which is the predominant feature of scleroderma, particularly as it affects the lungs, is secondary to these changes.

CASE-REPORTS

Case 1.—A married woman, aged 49, was well until fourteen years ago when she was admitted to North Cambridgeshire Hospital with fever, weakness, and generalised pains in the limbs and stiffness of the joints. This illness lasted for three months and was diagnosed as rheumatic fever. The pains persisted in the fingers, toes, knees, and spine. Raynaud's phenomena are described as occurring in the fingers during cold weather. Two years later the fingers began to contract into a fixed position of flexion, and subsequently the patient noticed difficulty in opening her eyes because the eyelids felt stiff. Intermittent dysphagia was first noticed at this time. Over a period of five years the patient lost 3 stone in weight.

In 1942 she was admitted to Addenbrooke's Hospital diagnosed as sclerodactyly. Examination then showed a milder degree of her present condition, save that there were no symptoms referable to the lungs and the X-ray films showed only slight pleural thickening at the right base. Other investigations at that time showed a basal metabolic rate (B.M.R.) of + 18%, negative Wassermann reaction, and a normal blood-count. Mantoux test (1 in 1000) was positive.

Six months ago she had an attack of laryngitis accompanied by pleurisy. Since then she has had troublesome dyspnœa on exertion and cough with up to an ounce of sputum per day. The scleroderma continues to progress slowly and she has now lost 4 stone in weight since the onset of the disease.

Family history: one sister suffers from stiffness of the fingers attributed to rheumatoid arthritis.

On examination, the patient is very emaciated with scanty body hair. The skin of the face is pigmented, stretched, and taut but not hard. The lips are thinned and contracted with radial furrowing. The nose is sharp and pinched with the skin drawn tightly over the cartilage. The fingers are fixed in a position of flexion of all the joints. There is slight clubbing of the nails and ulceration over some of the interphalangeal joints. The skin is shiny and pigmented over the fingers, hands, and in decreasing degree up the forearms. Hard pea-like subcutaneous nodules are palpable round both elbow-joints. Flexion of the knee-joints is limited to 90°. The tongue is smooth and depapilated. The trachea is deviated to the left. There is poor but equal expansion of the chest and an impaired percussion note over the left base where bronchial breathing is audible. There are râles and rhonchi over both lungs, most marked on the left side. No abnormalities were noted in other systems.

X-ray examination of the hands and forearms shows advanced rarification of the terminal phalanges, with calcareous deposits round the wrists and elbow-joints. X-ray films of the chest (fig. 1) show diffuse fibrosis, especially at the left base. A cyst is present at the left base and other fine cystic outlines are visible throughout the left lung. A bronchogram shows a mild degree of bronchiectasis, but the cysts were not entered by the iodised oil. A barium swallow showed no abnormality of the œsophagus.

SIR ADOLPHE ABRAHAMS

Fig. 1—Calcified arteries of leg.

Fig. 2—Calcified phalangeal artery of hallux.

DR. LORBER

Fig. 1—Case 6 on admission: miliary, with opacity in left lung. (*a*) 19 months later: opacity persists, with calcified mass in upper lobe.

Fig. 2—Case 14 on admission: miliary, with primary focus at right hilum. (*a*) After 6 months' treatment: lesion larger (fatal case).

Fig. 3—Case 18 on admission: miliary, with primary lesion at right hilum. (*a*) After 10 months' treatment: lesion much larger.

No tubercle bacilli were found in the sputum. Electrocardiogram and urinary creatinine output were normal. The urine contained no creatine. Red-cell count 3,740,000 per c.mm., Hb 10·4 g. per 100 ml., white cells normal.

Case 2.—A married woman, aged 47 years. In 1935, at the age of 33, she started to get typical Raynaud attacks, with "deadness" and pallor of the fingers. These attacks have gradually become more severe. The feet, ears, nose, and occasionally the tongue, are now similarly affected. At the same time she noticed that her skin was becoming darker and she began to suffer from epigastric pain and vomiting. Her symptoms at that time suggested a peptic ulcer but a barium meal in 1936 did not show an ulcer, though there was some dilatation of the stomach.

In 1937 she was admitted to Addenbrooke's Hospital and diagnosed as scleroderma with Raynaud's phenomenon. Chemical investigations gave no support to the possibility of her pigmentation being due to Addison's disease. (Blood-pressure 115/75 mm. Hg.) She was treated with injections of 'Padutin' with slight improvement. However, she continued to have attacks of abdominal pain and occasional episodes of diarrhœa. The spleen was repeatedly palpable at this time. She lost weight.

In 1944 she began to have dysphagia. Her food seemed to stick substernally. A barium swallow showed a tapering constriction at the lower end of the œsophagus; and follow-through showed considerable delay in the passage of barium with absence of the normal intestinal pattern and clumping of the barium. For her dysphagia she subsequently used a mercury bougie with considerable benefit.

In 1946 the vomiting became more severe and persistent. A gastroenterostomy was performed for pyloric stenosis. She continued to vomit occasionally after the operation and soon developed a cough with mucopurulent sputum. There was one small hæmoptysis and she became dyspnœic on effort. This was followed by a long illness with irregular fever and consolidation of the right lung, beginning in the right lower lobe (fig. 1). The process gradually spread to involve part of the right upper lobe. Many samples of her sputum were negative for tubercle bacilli. There was no leucocytosis but she had a considerable microcytic anæmia (Hb 8·2 g. per 100 ml.). Her weight had now fallen from $7^{1}/_{2}$ to 5 stone.

No appreciable response followed a full course of chemotherapy (sulphadimidine 35 g. and penicillin 8 mega units), but her fever slowly settled and the opacity in her right chest gradually resolved to leave a cystic appearance particularly affecting the right upper zone (fig. 2). There was also some residual fibrotic change in the left lung. The X-ray findings were reported on by Dr. F. R. Berridge, radiologist to Addenbrooke's Hospital, who correlated the lung changes with her scleroderma.

Since 1947 she has gradually improved and has gained weight. She is still dyspnœic on effort and has a troublesome cough with up to 1 oz. of sputum per day. Her anæmia has improved (Hb 11·0 g. per 100 ml.).

On examination she now has the typical pinched immobile facies of scleroderma with tightly stretched skin and fissures radiating from the corners of her mouth. Small telangiectatic spots are present on both cheeks and the lower lip. There is generalised pigmentation of the skin. The flexures, nipples, and her operation scar are not conspicuously pigmented but there is one small patch of pigmentation inside the right cheek. A few depigmented patches are present on the legs. The skin is dry and atrophic and there is induration of the subcutaneous tissues, especially of the forearms. A typical Raynaud's attack was witnessed during recent examination. There is some limitation of movement in the joints of the fingers and wrists, but no obvious deformity of the hands. Small superficial ulcers are present on the fingers. The patient also shows evidence (radiological only) of subcutaneous calcinosis in the upper extremities. Cardiovascular examination, including E.C.G., shows no abnormality. Her blood-pressure is now 130/80 mm. Hg. On routine examination the urine is also normal. Physical examination of the chest shows a pronounced dorsal kyphosis with poor but apparently equal expansion. Percussion note is impaired over the right upper chest and there are poor breath sounds and occasional crepitations over the same area. There are no clinical signs of cavitation, which suggests that there is no free communication between the cysts and the corresponding bronchi.

DISCUSSION

The onset of generalised scleroderma is commonly gradual with symptoms suggesting Raynaud's disease. This form of onset is differentiated into a distinct entity by Sellei (1934) and named acrosclerosis. Scleroderma may also begin with an acute afebrile illness and show many of the features of dermatomyositis, with which condition it was grouped by Dowling (1940). The 2 cases reported show this contrast in type of onset. Of the 9 cases described by Weiss et al. (1943), 6 presented as acrosclerosis and in 3 there was an acute febrile onset.

Involvement of the internal organs to such a degree as to be clinically detectable is usually a late manifestation of scleroderma, occurring in most reported cases years after the onset of symptoms. However the case of Wigley et al. (1949) suggests that pulmonary changes at least may precede the more common features of the disease.

The 2 cases reported here have been under observation for many years. In case 1 the lung changes became manifest with certainty less than seven years from the onset of the disease. The lung condition in case 2 has been observed developing during the last three years, ten years from the onset of symptoms. In this case the Raynaud's phenomenon, pigmentation, epigastric pain, and vomiting began simultaneously.

Dyspnœa is a common feature of all reported cases of fully developed pulmosclerosis and there is constantly a large reduction in the vital capacity, but the dyspnœa is often out of proportion to the lung damage. The mechanism of this dyspnœa is probably similar to that of cardiac dyspnœa and due to increased rigidity of the lung tissue. Cough is a common symptom, and the quantity of sputum depends on superadded infection, to which the subjects of pulmosclerosis are unduly liable. Pulmonary infection is commonly cited as a terminal event in uncomplicated scleroderma. It is probably often due to the favourable soil offered by undetected pulmonary sclerosis rather than to restriction of chest expansion.

Cystic changes in the lungs are an unusual finding in scleroderma. Clinically the changes produced are similar to those described in "honeycomb lung" (Oswald and Parkinson 1949). It is reasonable to suppose that the mechanism of cyst production is similar. Progressive fibrosis leads to bronchiolar obstruction. Areas of obstructive emphysema result from this, and ultimately when the obstruction becomes almost complete cysts are formed. This process of cyst formation, once begun, may be accelerated by fibrotic contraction of the surrounding tissues. In case 1 iodised oil introduced into the bronchial tree did not enter the cystic cavities, suggesting advanced stenosis of the communicating bronchioles.

Getzowa (1945) found that the epithelial lining of these cysts consisted of either cuboidal or columnar cells. More rarely ciliated epithelium may be present. No basement membrane was recognisable.

The widespread distribution of visceral lesions in scleroderma may clearly provide a difficult problem in diagnosis, and the underlying condition may be overlooked if examination is concentrated on the system predominantly affected. This is especially true of the lung changes in scleroderma, which show considerable variation both clinically and radiologically, and thus may mimic a number of lung conditions, notably bronchiectasis and chronic bronchitis, tuberculosis, "congenital cystic lungs," atypical and unresolved pneumonia, or fibrosis from other causes.

Although scleroderma may occur primarily in the skin, its name obscures the disseminated nature of the disease. Goetz (1945) suggested the adoption of the name progressive systemic sclerosis as more descriptive of the condition, and we agree.

Lung changes showing a similar histology are reported in disseminated lupus erythematosus (Klemperer 1948), and in rheumatoid arthritis (Ellman and Ball 1948). Clinically, rheumatoid arthritis has much in common with generalised scleroderma and has been reported in association with it (Ellman and Parkes Weber 1948). Lung changes are also reported in polyarteritis nodosa (Miller and Daley 1946). The X-ray changes show as increased vascular markings, particularly at the hila, and transitory infiltrations of the lower lobe regressing without residual abnormality. These changes are probably due to perivascular infiltration œdema and hæmorrhage. Permanent fibrosis is not reported.

Scleroderma and lupus erythematosis have been associated in the group of collagen vascular diseases, which also includes dermatomyositis and polyarteritis (Banks 1941). The diseases do not resemble one another clinically, and the appearance of lung affection, Raynaud's phenomenon, or renal involvement occasionally in all of them is understandable in view of the disseminated nature of the collagen vascular change.

The grouping together of these diseases is based largely on the histological findings, for perivascular cellular infiltration, endarteritis, and fibrinoid necrosis of the collagen ground substance of the arterial walls and surrounding connective tissue are present in all. The occurrence of similar changes in anaphylactic lesions of the lungs and other organs both experimentally produced in animals and as found at autopsy in patients with serum sickness (Rich and Gregory 1943, 1946) has been held to support the allergic theory of the ætiology of these diseases. However, the production of fibrinoid necrosis in collagen tissue has been described in a number of widely separated clinical diseases and experimentally produced conditions. It is recognised as occurring in malignant and experimentally produced hypertension, and locally it may be found in the base of peptic ulcers and in the vicinity of foreign bodies and abscesses (Baehr and Pollack 1947). These facts offer little support to the hypothesis of a common ætiology in these collagen vascular diseases.

SUMMARY

The published work on scleroderma with fibrosis of the lungs is reviewed.

Cystic pulmonary fibrosis is reported in two cases; these demonstrate the widespread nature of scleroderma, which is sometimes regarded as primarily a disease of the skin.

Scleroderma should be considered in the differential diagnosis of obscure fibrotic lung conditions, remembering that the lung lesion may occur without obvious skin changes.

The association with pulmonary lesions in other diseases of collagen tissue is discussed.

We are indebted to Dr. L. B. Cole and Dr. C. H. Whittle for permission to publish these cases, and to Dr. Ff. Roberts and Dr. F. R. Berridge for permission to reproduce the X-ray films.

CONSULTING PHYSICIAN, WESTMINSTER HOSPITAL, LONDON

With illustrations on plate

THE familiar saying that "a man is as old as his arteries" may be regarded either as a mere platitude repeated irresponsibly, or as a pointer to a convenient means of estimating general physique and viability. If we desire to apply it seriously we must first establish the criteria of arterial age.

The first difficulty is to distinguish between senile and pathological changes—a difficulty which is complicated by the uncertainty of deciding if so-called degeneration may be accepted as a normal process, and when the limit of what may be regarded as physiological is transcended; or, to put it simply, when senescence becomes senility. There is the further difficulty of selecting the arteries which provide an index of the circulatory system as a whole, since it is recognised that their vulnerability or resistance varies considerably. It is well known that the coronary arteries alone may be the seat of pathological changes, and that the cerebral vessels may be prematurely sclerosed independently of the arterial system as a whole. An estimation of life-expectation based on the condition of such vital structures must be very different from an estimation based on a presumably similar condition in vessels which are less directly related to survival and therefore to longevity.

Hence the observations recorded in this paper can have only a limited value, yet certain conclusions appear to be legitimate and worth presenting.

FINDINGS

Twenty-five years ago, after an athletic injury, X-ray examination of my lower limb revealed not only a fractured metatarsal but, rather unexpectedly, also calcification of the arteries. Having continued during the ensuing twenty-five years to take strenuous exercise in the form of running, fast walking, and climbing, I thought it might be worth while investigating the present state of these arteries. Skiagrams (fig. 1 and 2, on plate) show gross calcification in all the arteries of the lower limb, from the femoral artery down to the phalangeal artery of the great toe, including collateral vessels, particularly a subcutaneous vessel running over the calf. The arteries in the upper limb, however, are completely invisible radiographically. The thoracic and abdominal aorta similarly appears to be free from calcification.

A portion of a dorsalis pedis artery was excised and examined histologically. Sections stained with hæmatoxylin and eosin and with Weigert's elastic stain exhibit the features accepted as those of medial calcification (Mönckeberg's sclerosis). Projecting into the lumen at one point, but not causing any serious occlusion, is a strand of organised thrombus (fig. 3). The intima shows slight fibrous thickening but no true atheroma. The internal elastic lamina is fragmented and, at one or two places, reduplicated (fig. 4). The media shows calcification in the form of clearly circumscribed blocks of variable thickness apparently originating just below the inner elastic layer and at certain points spreading out almost to the adventitia (fig. 5). The surviving media exhibits advanced degeneration of the elastic and smooth muscle fibres with replacement by a lightly staining myxomatous stroma between the attenuated muscle-fibres (fig. 6). There is general dilatation of the vasa vasorum in the adventitia—presumably an attempt to improve the collateral circulation to compensate for any loss of contractility. Microscopy of an excised portion of a radial artery provides a striking contrast in all the features enumerated (fig. 7).

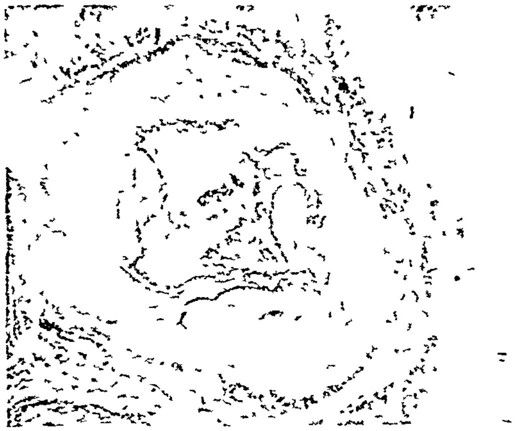

Fig. 4—Section of dorsalis pedis artery, showing reduplication and fragmentation of internal elastic lamina of intima. (Low power, Weigert's elastic stain.)

DISCUSSION

Medial calcification is generally held to be a degenerative process, and, as relating to the arteries of the leg,

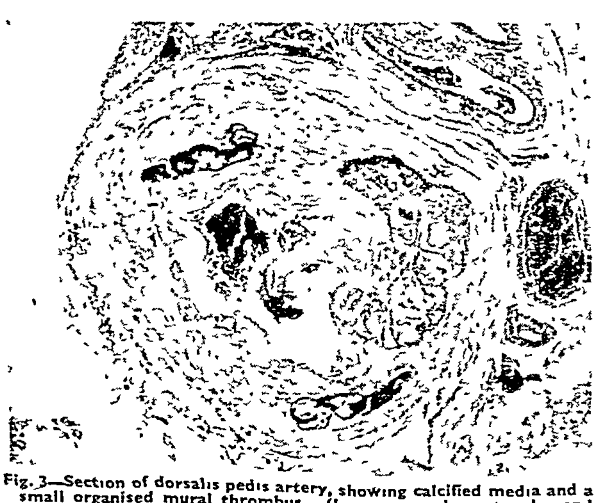

Fig. 3—Section of dorsalis pedis artery, showing calcified media and a small organised mural thrombus. (Low power, hæmatoxylin and eosin.)

* A communication to the Association of Physicians of Great Britain and Ireland, Belfast, June 4, 1949.

DISCUSSION

The onset of generalised scleroderma is commonly gradual with symptoms suggesting Raynaud's disease. This form of onset is differentiated into a distinct entity by Sellei (1934) and named acrosclerosis. Scleroderma may also begin with an acute afebrile illness and show many of the features of dermatomyositis, with which condition it was grouped by Dowling (1940). The 2 cases reported show this contrast in type of onset. Of the 9 cases described by Weiss et al. (1943), 6 presented as acrosclerosis and in 3 there was an acute febrile onset.

Involvement of the internal organs to such a degree as to be clinically detectable is usually a late manifestation of scleroderma, occurring in most reported cases years after the onset of symptoms. However the case of Wigley et al. (1949) suggests that pulmonary changes at least may precede the more common features of the disease.

The 2 cases reported here have been under observation for many years. In case 1 the lung changes became manifest with certainty less than seven years from the onset of the disease. The lung condition in case 2 has been observed developing during the last three years, ten years from the onset of symptoms. In this case the Raynaud's phenomenon, pigmentation, epigastric pain, and vomiting began simultaneously.

Dyspnœa is a common feature of all reported cases of fully developed pulmosclerosis and there is constantly a large reduction in the vital capacity, but the dyspnœa is often out of proportion to the lung damage. The mechanism of this dyspnœa is probably similar to that of cardiac dyspnœa and due to increased rigidity of the lung tissue. Cough is a common symptom, and the quantity of sputum depends on superadded infection, to which the subjects of pulmosclerosis are unduly liable. Pulmonary infection is commonly cited as a terminal event in uncomplicated scleroderma. It is probably often due to the favourable soil offered by undetected pulmonary sclerosis rather than to restriction of chest expansion.

Cystic changes in the lungs are an unusual finding in scleroderma. Clinically the changes produced are similar to those described in "honeycomb lung" (Oswald and Parkinson 1949). It is reasonable to suppose that the mechanism of cyst production is similar. Progressive fibrosis leads to bronchiolar obstruction. Areas of obstructive emphysema result from this, and ultimately when the obstruction becomes almost complete cysts are formed. This process of cyst formation, once begun, may be accelerated by fibrotic contraction of the surrounding tissues. In case 1 iodised oil introduced into the bronchial tree did not enter the cystic cavities, suggesting advanced stenosis of the communicating bronchioles.

Getzowa (1945) found that the epithelial lining of these cysts consisted of either cuboidal or columnar cells. More rarely ciliated epithelium may be present. No basement membrane was recognisable.

The widespread distribution of visceral lesions in scleroderma may clearly provide a difficult problem in diagnosis, and the underlying condition may be overlooked if examination is concentrated on the system predominantly affected. This is especially true of the lung changes in scleroderma, which show considerable variation both clinically and radiologically, and thus may mimic a number of lung conditions, notably bronchiectasis and chronic bronchitis, tuberculosis, "congenital cystic lungs," atypical and unresolved pneumonia, or fibrosis from other causes.

Although scleroderma may occur primarily in the skin, its name obscures the disseminated nature of the disease. Goetz (1945) suggested the adoption of the name progressive systemic sclerosis as more descriptive of the condition, and we agree.

Lung changes showing a similar histology are reported in disseminated lupus erythematosus (Klemperer 1948), and in rheumatoid arthritis (Ellman and Ball 1948). Clinically, rheumatoid arthritis has much in common with generalised scleroderma and has been reported in association with it (Ellman and Parkes Weber 1948). Lung changes are also reported in polyarteritis nodosa (Miller and Daley 1946). The X-ray changes show as increased vascular markings, particularly at the hila, and transitory infiltrations of the lower lobe regressing without residual abnormality. These changes are probably due to perivascular infiltration œdema and hæmorrhage. Permanent fibrosis is not reported.

Scleroderma and lupus erythematosis have been associated in the group of collagen vascular diseases, which also includes dermatomyositis and polyarteritis (Banks 1941). The diseases do not resemble one another clinically, and the appearance of lung affection, Raynaud's phenomenon, or renal involvement occasionally in all of them is understandable in view of the disseminated nature of the collagen vascular change.

The grouping together of these diseases is based largely on the histological findings, for perivascular cellular infiltration, endarteritis, and fibrinoid necrosis of the collagen ground substance of the arterial walls and surrounding connective tissue are present in all. The occurrence of similar changes in anaphylactic lesions of the lungs and other organs both experimentally produced in animals and as found at autopsy in patients with serum sickness (Rich and Gregory 1943, 1946) has been held to support the allergic theory of the ætiology of these diseases. However, the production of fibrinoid necrosis in collagen tissue has been described in a number of widely separated clinical diseases and experimentally produced conditions. It is recognised as occurring in malignant and experimentally produced hypertension, and locally it may be found in the base of peptic ulcers and in the vicinity of foreign bodies and abscesses (Baehr and Pollack 1947). These facts offer little support to the hypothesis of a common ætiology in these collagen vascular diseases.

SUMMARY

The published work on scleroderma with fibrosis of the lungs is reviewed.

Cystic pulmonary fibrosis is reported in two cases; these demonstrate the widespread nature of scleroderma, which is sometimes regarded as primarily a disease of the skin.

Scleroderma should be considered in the differential diagnosis of obscure fibrotic lung conditions, remembering that the lung lesion may occur without obvious skin changes.

The association with pulmonary lesions in other diseases of collagen tissue is discussed.

We are indebted to Dr. L. B. Cole and Dr. C. H. Whittle for permission to publish these cases, and to Dr. Ff. Roberts and Dr. F. R. Berridge for permission to reproduce the X-ray films.

without further treatment (see below), though the healing is much slower than with penicillin, aureomycin, or even chloramphenicol. Thus, if soft sores are treated with penicillin, streptomycin, aureomycin, or chloramphenicol (all of which seem to have some action in the natural infection if given in sufficient dosage), the patient should be observed for 2 years in case a concomitant syphilitic infection has been missed. However, streptomycin seems to be the most effective antibiotic against soft sore. In-vitro tests by Wetherbee et al. (1949) confirm this view and suggest that penicillin and aureomycin are only slightly active.

So far in this country there has been little confirmation of the American work, partly because soft sore is comparatively uncommon here but more especially because streptomycin has been largely reserved for more serious conditions. The following case-records indicate the effectiveness of quite small doses of the drug.

Case 1.—A young male native of Southern Rhodesia reported in May, 1949, with two preputial sores of 4 days' duration and a developing right bubo. No gonococci were found in the urethral smear, three daily dark-field examinations of material from the sores were negative for *T. pallidum*, and the Wassermann, Kahn, and Ide tests on his blood were negative. Ducrey's bacilli were found in the sores, and the Dmelcos skin test for chancroid was positive. The lygranum skin test for lymphogranuloma venereum was negative. The patient was given the small dose of 0·5 g. of streptomycin daily for 4 days (total 2 g.). The Ducrey's bacilli disappeared from the sore, the sore healed, the bubo subsided without fluctuation, and the patient was considered fit for discharge on the 5th day. The bubo was not aspirated.

Case 2.—A young male native of Southern Rhodesia reported with two preputial sores and a developing left bubo, having had his last sexual exposure 10 days before. No gonococci were seen in the urethral smear, three dark-field examinations of material from the sores were negative for *T. pallidum*, and the Wassermann, Kahn, and Ide tests on his blood and the lygranum skin test were all negative. Ducrey's bacilli, however, were found in smears from the sores, and the Dmelcos skin test was positive. He was given 0·5 g. of streptomycin once daily for 5 days (total 2·5 g.). The Ducrey's bacilli disappeared from the sores, which healed by the 7th day. The bubo, however, fluctuated and was aspirated on the 4th day.

Case 3.—A young male native of Portuguese East Africa reported with multiple preputial sores and a right inguinal bubo, having had his last sexual exposure 7 days before. The urethral smear was negative for gonococci, two dark-field examinations did not show *T. pallidum*, and the lygranum skin test was negative. The Wassermann, Kahn, and Ide tests on his blood were also negative, but the Dmelcos skin test was positive. He was given eight daily injections of 0·5 g. of streptomycin intramuscularly (total 4 g.). The sore was slow in healing but had healed by the 12th day. The bubo required two aspirations, on the 5th and 9th days.

Case 4.—A young male native of Southern Rhodesia reported with two ulcers on the prepuce but no inguinal adenitis. His last sexual exposure had been 5 days before. No gonococci were found in the urethral smear, three dark-field examinations of material from the sores were negative for *T. pallidum*, and the Wassermann, Kahn, and Ide reactions of his blood were negative. The lygranum test was negative, but the Dmelcos skin test was positive. He received nine daily injections of 0·5 g. of streptomycin (total 4·5 g.). The sore healed by the 9th day.

Case 5.—A male native of Southern Rhodesia reported, 7 days after intercourse, with preputial sores without enlargement of the inguinal glands. The urethral smear showed no gonococci, two dark-field examinations were negative for *T. pallidum*, and the Wassermann, Kahn, and Ide tests on his blood were negative. The Dmelcos and lygranum skin tests were also negative but Ducrey's bacilli were found in smears from the sore. He was given three daily injections of only 0·5 g. of streptomycin, and the Ducrey's bacilli disappeared from the sore, which healed on the 3rd day, after which the patient was discharged. He relapsed, however, and, denying further exposure, returned 17 days later with multiple preputial sores and tender non-fluctuant but enlarged inguinal glands of 5 days' duration. The sores healed, and the developing bubo subsided without aspiration, after treatment with only four daily injections of 0·5 g. of streptomycin.

Case 6.—A male native of Southern Rhodesia reported with a rosette of soft sores on the prepuce and a developing right bubo. Smears from the urethra showed no gonococci, repeated dark-field examinations of material from the sores were negative for *T. pallidum*, and the blood Wassermann reaction was negative. The Dmelcos and lygranum skin tests were also negative. He was given four daily injections of 1 g. of streptomycin (total 4 g.). The bubo required aspiration on the 2nd day, but the sores healed in 3 days and he was discharged on the 5th day.

Case 7.—A male native of Nyasaland reported with a rosette of preputial sores without inguinal adenitis. Dark-field examinations of material from the sores were negative for *T. pallidum*, and the Wassermann reaction of the blood was negative, but the Dmelcos skin test was positive. Gonococci, however, were found in a purulent discharge from the urethra. The patient received 1 g. of streptomycin twice daily on the 1st day and a single injection of 1 g. on the 2nd day (total 4 g.). The urethral discharge disappeared at once, and the urine became clear in 24 hours. The sores healed by the 3rd day.

EFFECTS OF STREPTOMYCIN ON EARLY SYPHILITIC LESIONS

It has already been shown (Willcox 1948) that a small single dose of streptomycin, up to 0·6 g. as used for gonorrhœa, is insufficient to banish *T. pallidum* from a syphilitic chancre. Therefore in three cases of early syphilis repeated doses of streptomycin, such as might be used for soft sore were tried. It was found that the larger doses could abolish *T. pallidum* from the dark field and that thereafter the sores slowly but completely healed.

The three patients treated were all natives with typical primary syphilis. One was from Portuguese East Africa, and the remainder were from Southern Rhodesia. In one the chancres were multiple and in the others single. One was seronegative and the others were seropositive. All, however, showed typical syphilitic enlargement of the inguinal glands, and from all of them *T. pallidum* was recovered without difficulty.

One patient was given 1 g. of streptomycin three times a day for 2 days followed by 1 g. on the 3rd day (total 7 g.). The dark fields were negative at 24 hours and thereafter daily for the next 7 days. The sore healed slowly and had completely healed by the 11th day.

The second patient was given 1 g. of streptomycin twice daily for a day and 1 g. in two divided doses on the second day (total 3 g.). The dark field was still positive at 24 hours, and *T. pallidum* was again isolated, albeit with considerable difficulty, at 48 hours. Daily dark fields for the next 5 days, however, were negative, and the sore healed slowly by the 10th day.

The third patient received 1 g. of streptomycin twice daily for a day and 1 g. in divided doses on the 2nd and 3rd days (total 4 g.). The dark field remained positive at 24 hours and again at 48 hours. Thereafter it was negative for the next 4 days, and the sores healed without further treatment by the 10th day.

STREPTOMYCIN IN EXPERIMENTAL *H. ducreyi* INFECTION

The effectiveness of streptomycin against chancroid was tested in another way. Chancroid is readily inoculable; indeed, before it was recognised to be distinct from syphilis, deliberate inoculation was, for a time, a well-recognised treatment (syphilisation).

An intradermal injection of unsterilised bubo fluid from an untreated person will, in 48–72 hours, produce a small pustule which, if the person is untreated, will develop into an ulcer within the usual incubation

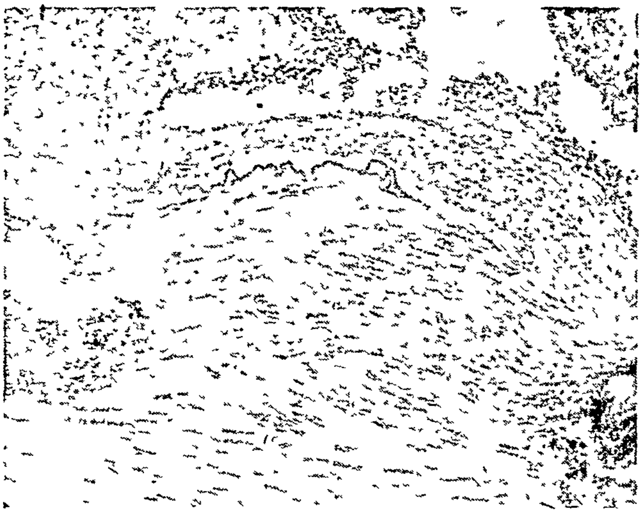

Fig. 6—Section of dorsalis pedis artery, showing degeneration of muscle-fibres in media. (High power, hæmatoxylin and eosin.)

a more or less normal one after the fifth decade. It is highly probable that appropriate investigation would reveal the onset in a considerable number of cases at an earlier age than that usually accepted. Since what is regarded as a senile change is in question, whether or no the term physiological may be used as synonymous, it is not easy to estimate the effect of exercise in the direction of aggravation, for very little material is available to investigate the influence of strenuous activity in middle and old age as these epochs are generally understood. Certain occupations which necessitate either long periods of standing or of protracted locomotion might provide information—e.g., those of waiters or postmen.

Medial calcification is relatively infrequent in the subjects of thromboangiitis obliterans. This suggests that occlusion, with non-functioning arteries, protects against calcification. If activity is a responsible factor, a high degree of Monckeberg's sclerosis would be expected in the vessels of the arms in those whose occupation demands vigorous use of the upper limbs, but I am not aware of any such observation.

What explanation is forthcoming for the far greater incidence in the vessels of the lower limbs of both medial calcification and Buerger's disease, though entirely different processes are concerned and it seems that activity is not responsible ? Is it the greater blood-pressure resulting from the erect attitude which operates for a considerable portion of the twenty-four hours of each day ?

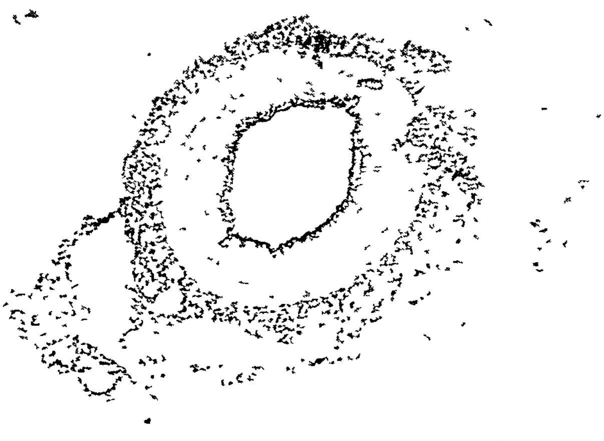

Fig. 7—Section of radial artery, showing no abnormality. (Low power, Weigert's elastic stain.)

The possibility of biochemical influence has to be remembered, and from time to time various hypotheses have been advanced about arteriosclerosis, especially in connection with the coronary arteries, but calcification appears to be in an isolated category. In my own case the serum-cholesterol has been found to be 168 mg. per 100 ml., the serum-calcium 10·4 mg. per 100 ml., and the plasma-inorganic phosphates 3·8 mg. per 100 ml. It is doubtful whether any useful deductions can be drawn from figures that are regarded as within normal limits.

It is not easy to take an objective view of a personal investigation. Symptoms which might be interpreted as evidence of circulatory inadequacy in the small peripheral vessels may be explainable as the exponent of a constitutional vasomotor dysfunction and quite unrelated to the conditions under consideration.

One criterion seems reasonably valid. The extensive calcification and the presumed reduction of contractility of the arteries can scarcely have caused substantial vascular impairment; for no muscular pain (so-called intermittent claudication) was noted even on the performance of such exercise as running nine miles in the hour.

SUMMARY

Extensive calcification of the vessels of the lower limb having been radiographically identified, a portion of a dorsalis pedis artery was excised and showed the features of Mönckeberg's sclerosis. A considerable amount of strenuous exercise could nevertheless be taken without giving rise to any muscular pain whatever. Evidently a high degree of medial calcification is compatible with circulatory efficiency.

I am greatly indebted to colleagues in various departments of Westminster Hospital for their generous cooperation.

STREPTOMYCIN IN SOFT SORE

OBSERVATIONS ON CLINICAL AND EXPERIMENTAL INFECTIONS

R. R. WILLCOX
M.B. Lond.

PHYSICIAN IN CHARGE OF VENEREAL DISEASES DEPARTMENT
KING EDWARD VII HOSPITAL, WINDSOR. CONSULTANT
VENEREOLOGIST, ST. MARY'S HOSPITAL, PADDINGTON

IT is over 3 years now since Mortara and Saito (1946) showed that *Hæmophilus ducreyi* is sensitive to streptomycin, and in 1947 they demonstrated that streptomycin could prevent the appearance of chancroid in experimentally infected animals. The first results with the drug in the natural infection in man were reported by Hirsh and Taggart (1948), who treated fifteen patients with 1 g. daily in divided doses until the sores had healed, which took 5–25 days. Some of their patients were followed up for only a short time, and there was one possible recurrence at 6 weeks.

Streptomycin has one possible advantage which is not possessed by the sulphonamides or by penicillin, 'Aureomycin,' or chloramphenicol—that in small doses it has only a slight action on syphilis and thus does not appreciably affect the results of dark-field examinations. Thus (Willcox 1948) *Treponema pallidum* were found without difficulty in a primary chancre 24 hours after the patient had been given a single injection of streptomycin 0 6 g., a dose curative for gonorrhœa. It seemed therefore that streptomycin given in such doses for gonorrhœa, was unlikely to screen a simultaneous syphilitic infection. Larger doses, however, may banish *T. pallidum* from a chancre, and syphilitic sores may subsequently heal

After operation she was treated with continuous gastric suction for 24 hours and then for 3 days the stomach was aspirated twice a day. The residue averaged 2 oz. On the 8th day she was distended and gastric aspiration produced 60 oz. Aspiration of the stomach thrice daily was then started. On Feb. 28 a barium meal showed slow emptying of the stomach, with a third of the barium still in the stomach after 4½ hours.

At this time she started to have diarrhœa, the bowels moving about three times during the night but not during the day. She also complained of feeling bloated. An insulin test on March 12 showed no rise in gastric acidity after intravenous injection of 15 units of insulin.

At outpatient follow-up she complained of constant heartburn, and said she was so distended in the evenings that she could not wear her usual clothes, and spent the evenings in a dressing-gown. She had periods of vomiting when she brought up large quantities at intervals of two or three days. She stated that she had none of the original ulcer pain but could not decide whether the heartburn and distension were preferable to it. She was seen on April 13, 1949, and at that time it was thought that a gastro-enterostomy would almost certainly be necessary.

Second Admission

On May 11, 1949, she was admitted at midday with a history of very severe pain in the belly, which had started suddenly 2 hours previously. The pain was constant, worst in the upper abdomen, and did not radiate; there was no pain in the shoulder or back. She had vomited repeatedly and copiously since its onset. She was pale with a cyanotic tinge and looked very ill. Her pulse-rate was 80 per min., regular but almost imperceptible. Her systolic blood-pressure was 50 mm. Hg and the diastolic pressure could not be recorded. There was no trace of rigidity, and the posterior abdominal wall could be palpated easily from in front. Nevertheless the abdomen was exquisitely tender to touch; no mass was palpable, and gut sounds were present. Palpation of the pouch of Douglas per rectum was painful. A systolic murmur was heard at the apex. There was no sign of pneumothorax.

A perforated peptic ulcer was the probable diagnosis, but the complete absence of any rigidity and the severity of the shock suggested a coronary thrombosis. Radiography showed much gas under the diaphragm.

Her condition improved gradually and a plasma transfusion was started. Not until 1 A.M. on the 12th—15 hours after perforation—when her blood-pressure was 90/65 mm. Hg, was she deemed fit for operation.

Second Operation: Suture of Perforated Duodenal Ulcer

Through a small transverse incision, which preserved the recti though opening the rectus sheath on each side, a large quantity of clear fluid was seen and there was a considerable escape of gas from the peritoneal cavity. A perforation about ⅛ in. across was found on the anterior wall of the first part of the duodenum. This was sutured and a drain through a suprapubic stab wound was left in the pouch of Douglas.

She was treated with continuous gastric suction for 48 hours and then by repeated aspirations of the stomach. The aspirations were discontinued on May 21, but recommenced on the 26th, after she had become distended and a splash was heard. She was aspirated daily till June 8, when, with plasma-protein 6% and hæmoglobin 74%, she was considered fit for a partial gastrectomy.

Third Operation: Partial Gastrectomy

A Polya Hoffmeister antecolic partial gastrectomy was performed. The duodenum was divided distal to the ulcer and about four-fifths of the stomach was removed. She was given two pints of blood during the operation and her condition on leaving the table was good.

After the operation she was treated by continuous gastric suction for 48 hours and then stomach aspiration thrice daily. Gut sounds returned on the 3rd postoperative day and on the 4th day she said she had passed "the merest zephyr" of wind. In view of her vagotomy and previous gastric retention, daily gastric aspiration was continued until the 9th day.

Since the gastrectomy she has complained of weakness, but is pleased with the condition of her stomach. She has no pain, vomiting, or distension, and she enjoys her food.

DISCUSSION

Alvarez (1948), discussing vagotomy, says that there have been a few cases in which some time after the operation an ulcer has perforated without producing the usual paralysing pain. He refers to a case reported by Walters et al. (1947). The *British Medical Journal* (1948) repeats this statement, and, when asked by Johnson (1948) for details, refers to Walters's case.

I have been able to trace only two reported cases of perforation after vagotomy and not much detail is given about either of them.

In the one described by Walters et al. the patient died 14 days after transabdominal vagotomy and gastro-enterostomy for duodenal ulcer. A perforation had not been suspected but at necropsy a perforated duodenal ulcer and a subphrenic abscess were found. In this case, despite the gastro-enterostomy, there had been considerable postoperative gastric retention.

The other case, reported by Weeks et al. (1946), was that of an alcoholic hypertensive patient who had a duodenal ulcer of 15 years' standing. At the first operation a transthoracic vagotomy and a left thoracolumbar sympathectomy were performed. There was some postoperative gastric retention. After 13 days a right thoracolumbar sympathectomy was performed and 6 days later the patient became confused and obstreperous. On the 15th day after the second operation he complained of pain in the lower abdomen, and slight diffuse abdominal tenderness was found. Examination was difficult because of his lack of coöperation. At necropsy a perforated duodenal ulcer 2·5 cm. in diameter was found.

The issue in both of these cases is confused by the additional procedures performed—in one a gastro-enterostomy and in the other a thoracolumbar sympathectomy.

The present case differs from these two cases in many ways. The ulcer perforated 15 months after vagotomy and not in the postoperative period. It is well known that perforation of viscera, or intraperitoneal leak from a suture line in the early postoperative period, may occur with very little pain, and in fact this is one of the most difficult conditions to diagnose; but this patient suffered very severe pain. The most remarkable feature was the complete lack of rigidity, the abdomen being soft but intensely tender. In the two American cases there is no mention of rigidity, though the impression given is that rigidity, if present, was slight. Until radiography showed much gas under the diaphragm, the diagnosis in the present case was in doubt. The lack of rigidity might be attributed to the shock, which was profound—the systolic blood-pressure being 50 mm. Hg on admission. But even when the systolic pressure reached 90 mm. Hg there was still no rigidity. The other suggestion is that division of the vagi in some way interfered with the appearance of rigidity, though it has been widely held that abdominal rigidity is due to a segmental spinal reflex, the vagus pathway not being involved.

Why the ulcer perforated is uncertain. At the time of vagotomy the pyloric canal was the size of a little finger and there was severe postoperative retention of the gastric contents. This was also noted in the other two reported cases. The most obvious contention would be that the vagotomy was not complete: but the postoperative insulin test was satisfactory, and she developed two of the common complications of adequate vagotomy—namely, diarrhœa and a feeling of distension after food.

In the light of experience I should probably not do a vagotomy on a patient with as much stenosis as this one had. I now do vagotomy only in cases of duodenal ulcer where stenosis is very slight: in all others operated on I prefer to do a high partial gastrectomy, rather than confuse the issue by combining vagotomy with some additional procedure such as gastro-enterostomy or antrectomy.

period of the disease. Such ulceration may be avoided by needling the pustule and treating with appropriate systemic drugs, whose relative effectiveness may be tested in this way. Such a method, however, involves a positive take in every case and is therefore less suitable than the methods to be described.

If inoculated persons are treated with the drugs to be tested at the time of inoculation, a "take" is only to be expected in the failures of treatment. Either the fluid may be obtained from the recipient's own bubo, in which case no controls are available, or hetero-inoculations may be used with proper controls in volunteers. A second method is to test the virulence of a given bubo by inoculation into a volunteer and then treat the patient with the drug to be tested, serial inoculations being made into volunteers at various times after the start of treatment. Both methods limit the numbers of positive takes, and both were used with streptomycin.

Three patients with chancroidal buboes had 0·05 ml. of bubo fluid injected intradermally into their own forearms and were treated with 0·5–1·0 g. of streptomycin daily for 3 days. In none did a pustule form; in one case a small non-tender papule formed at 48 hours and disappeared within 96 hours of inoculation. The objection to this method is that there can be no control apart from an injection of the same material into another person, which cannot be regarded as a strict comparison.

Seven other volunteers, therefore, received hetero-inoculations from four donors and were treated with 1·5–6·0 g. of streptomycin over 2–5 days. In none did a pustule develop, though one showed a well-marked indurated papule at 96 hours, which was not needled and, in the light of later experience, was possibly a minor take. Fourteen of sixteen controls, on the other hand, given similar inoculations from the same four donors but receiving no systemic treatment, developed the pustular reaction, which was aborted by needle aspiration and with suitable drugs, of which streptomycin was found to be one.

In addition, two patients with chancroidal buboes were shown to have virulent fluid in so far as the pustular reaction developed in two out of the three controls injected. The donors were given 1–2 g. of streptomycin daily, and intradermal injections of 0·05 ml. of aspirated bubo fluid were made each day into others. The first donor received 2 g. of streptomycin on the 1st day and thereafter 1 g. daily for 3 days. Intradermal injections were made into the forearms of four others 24, 48, and 72 hours after the start of treatment without producing a pustular or ulcerative reaction in any of them. Incidentally, the donor of this series was discharged with the bubo subsided and the sore healed 5 days after treatment with streptomycin. The second donor received 3 g. of streptomycin in 3 days, and injections of the bubo fluid were made into five volunteers 24 and 48 hours after the beginning of treatment without producing a reaction in any of them.

SUMMARY AND CONCLUSIONS

Eight African negroes with soft sore were treated with 1·5–5·0 g. of streptomycin in 2–9 days. No adverse effects were noted.

The sores healed in an average of 6 days. Four out of five actual or developing buboes required aspiration. There was one known relapse.

Three patients in whom dark-field examinations showed primary syphilis were given 3–7 g. of streptomycin in 2 or 3 days. At 24 hours the dark-field examination was negative in one and positive in two, in both of which *T. pallidum* was again recovered with difficulty at 48 hours. Subsequently daily dark-field examinations were made in all the cases until the sores had healed, with negative results. Healing was slow, taking 10–11 days.

Ten persons received injections of 0·05 ml. of bubo fluid of proved virulence intradermally into the forearm and were treated with 1·5–6 g. of streptomycin in 2–5 days. In none did a reaction develop, though fourteen of sixteen controls showed a positive result.

Injection of bubo fluid of previously proved virulence from two persons with chancroidal buboes treated with streptomycin into the arms of nine others 24–72 hours after the start of treatment also did not provoke a single reaction.

It is confirmed that streptomycin is effective against soft sore both in natural and in experimental infection. It may be inferred from the experiments described that it is also prophylactic.

Streptomycin has some action on a syphilitic infection when given in sustained dosage.

The sulphonamides continue to be the drugs of choice for the treatment of chancroid. They are just as effective and, if properly handled, no more toxic, but have no action on syphilis, and therefore a follow-up of only 3 months is necessary after treatment to exclude a tardy syphilitic infection, whereas, if streptomycin is used, the follow-up should be longer.

PERFORATION OF A DUODENAL ULCER FIFTEEN MONTHS AFTER VAGOTOMY

H. A. DANIELS
M.Ch. Dubl., F.R.C.S., F.R.C.S.I.
SENIOR SURGICAL REGISTRAR, NORTH MIDDLESEX HOSPITAL

PERFORATION of a duodenal ulcer after vagotomy is one of the rarer complications of this operation, and the following case seems to be the first reported example of a late perforation after vagotomy.

CASE-RECORD

A retired schoolmistress was 65 years old when she was admitted to hospital on Dec. 18, 1947, having vomited about a pint of "coffee grounds" 4 days previously. She had fainted the day before admission and passed a black stool.

She had a 24 years' history of recurrent attacks of abdominal pain and vomiting. The attacks lasted about a fortnight with intervals of 2–3 months. She had had two attacks of hæmatemesis, one 24 years and one 21 years ago. She had lost her appetite for a few months before admission but had no recent vomiting.

Her general condition was fair. The abdomen was scaphoid and there was no tenderness or mass. The blood-pressure was 140/80 mm. Hg and the hæmoglobin 70%. A barium meal showed deformity in the region of the pylorus, but the radiologist could not say on which side of the pylorus the lesion was. Gastroscopy did not reveal any lesion of the stomach, but a good view of the antrum was not obtained. An insulin test showed a steep rise in gastric acidity after 15 units of insulin given intravenously, and a high resting acidity.

First Operation (Feb. 6, 1948): Vagotomy

At operation a duodenal ulcer was found, with the duodenal lumen narrowed down to the size of the little finger. A strong band crossing the pyloric antrum probably accounted for the radiologist's doubts in diagnosis. As the stenosis was not regarded as excessive, a trans-hiatal vagotomy was performed, about 3 in. of each vagus being resected. An isolated branch of the right vagus was also resected. At the same time a right ovarian cyst was excised after enlarging the incision downwards.

Reviews of Books

Urological Aspects of Spinal Cord Injuries

George C. Prather, M.D., department of genito-urinary surgery, Harvard Medical School, Boston, Mass. Oxford: Blackwell Scientific Publications. 1949. Pp. 146. 27*s*.

The danger of forgetting the lessons of war is as great in medicine and surgery as in the military arts. At the outbreak of the second world war there was no settled policy for the treatment of the bladder in spinal injuries, and despite advances made in the light of increased experience there are still many differences of opinion on the right methods to use. This monograph, setting out the evidence available, should revive interest in a problem which still awaits final solution. The opening section on the anatomy, nerve-supply, and physiology of the normal bladder at once reveals some conflicting views, but summarises those generally accepted. The term "internal sphincter" is retained for convenience, but with the proviso that it does *not* denote a circular arrangement of muscle at the bladder neck. In line also with modern concepts is the belief that sympathetic-parasympathetic antagonism does not hold good in the bladder. The changes in bladder function after spinal-cord injury are clearly described; Dr. Prather recognises three stages of recovery, the atonic neurogenic bladder, the autonomous bladder, and the periodic reflex automatic bladder of complete transection, or the voluntary neurogenic bladder of partial transection. This perhaps oversimplifies a complicated subject, and no mention is made of the not uncommon longitudinal spinal lesion. The special methods of examination of the bladder by cystometry, cystoscopy, and cystography are described, with reliance placed on cystometry as an index of progress. He rightly demands that cystoscopy in these cases should only be done by an expert. Ureteric reflux in cystography is found to be uncommon, and is ascribed to inflammation rather than to the effect of the nerve lesion.

The care of the paralysed bladder is discussed; whatever may be the outcome of the arguments between urethral and suprapubic catheter drainage Dr. Prather is of the opinion, shared by most competent observers, that intermittent catheter drainage, is the worst form of immediate treatment. In the early stages he accepts either urethral or suprapubic continuous drainage, with either manual or automatic (tidal) irrigation. His criterion for abandoning the urethral catheter is the severity of the case, as assessed by further neurological examination. Where drainage for more than a few weeks is required, he prefers the suprapubic route, and recognises the need for a high opening. Bladder-neck resection is used selectively and only when the maximum neurogenic activity has been attained. There is a good section on the genito-urinary complications, including those due to a urethral catheter. He gives the results of treatment in his own cases as well as those of others, and British surgeons will share most of his opinions. It is interesting that, despite an official programme of urethral tidal-drainage ordered by the U.S. Chief Surgeon in the European theatre of operations before D-day, it was not long before patients began to return with suprapubic tubes. Suprapubic drainage was the official British policy and undoubtedly paid handsomely. A good bibliography, which does not neglect British work on the subject, completes a useful book.

The Natural History of Mosquitoes

Marston Bates. New York and London: Macmillan. 1949. Pp. 379. 25*s*.

This book is neither a handbook to the mosquitoes of the world, nor a medical text, but a true natural history, covering both our knowledge of mosquitoes in the field and our attempts to analyse our observations in the laboratory. Dr. Bates dislikes the division of biology into "self-important little sciences, each preoccupied with the accumulation of its own peculiar kind of facts, according to the forms and rituals that are prescribed by its traditions." His book is therefore a collection of all sorts of information about living mosquitoes, beginning with an account of the differences in the ways of life of various species, as well as of their similarities. He holds that cryptic species (i.e., species which are physiologically distinct, but difficult to separate on anatomical points) have a real value in systematics; and certainly such distinctions are most useful in the field identification of any animal. This section is separated, by chapters on the relation of mosquitoes to pathogenic organisms, from a section entirely devoted to the species problem—an arrangement which entails some irritating repetition. In dealing with the enemies of mosquitoes, and the rôle of mosquitoes as vectors of human disease, Dr. Bates has not emphasised the medical aspect of mosquito biology; but in the chapter on the strategy of mosquito research he uses the considerable body of knowledge collected through medical research on mosquitoes. The time has undoubtedly come for the academic biologist to use this knowledge as the start of more critical studies of mosquito populations, for it is on such analyses that successful mosquito control might be built. Dr. Bates has made a useful contribution to this end.

Metabolic Interrelations

Transactions of the first conference, Feb. 7–8, 1949. Editor: Edward C. Reifenstein, M.D. New York: Josiah Macy, Junior, Foundation. 1949. Pp. 193. $2.95.

Biological Antioxidants

Transactions of the third conference, Oct. 7–8, 1948. Editor: Cosmo G. Mackenzie. New York: Josiah Macy, Junior, Foundation. 1949. Pp. 146. $2.70.

The Josiah Macy, Junior, Foundation sponsors a number of conferences of special investigators representing, so far as possible, all the branches of science which bear on a particular problem. The proceedings of the conferences are published, and we have reviewed a number of those on convalescence. The transactions of the first of the conferences on metabolic interrelations consist of a series of 19 papers, and that of the third conference on biological antioxidants of 10 papers, each followed by a long discussion, reported at full length, after the pattern laid down for other conferences. The authors of the papers are all experts in their own fields, and each of their contributions demands a considerable degree of specialised knowledge on the part of the reader. These conferences must certainly be most useful and stimulating to the participants; but it is doubtful whether those who were not at the conference will find the papers more useful in this form than as articles appearing in the usual way in the scientific journals. If these transactions continue to appear regularly, and if they acquire reputations comparable to those of the well-known scientific journals, they will find their place in scientific literature; the papers will be abstracted and it will be easy to obtain access to them. Unless that happens few people in this country are likely to get them, and it is difficult therefore to appraise their future value to British scientists.

Vitamins and Hormones

Vol. VII. Editors: Robert S. Harris; Kenneth V. Thimann. New York: Academic Press. 1949. Pp. 488. $7·80.

This volume is similar in substance to others in this series. It contains 13 articles, and some are inevitably more readable or stimulating than others. The only one by British authors is on the puzzling subject of vitamin P.

On the physiology of aneurin, Prof. B. C. P. Jansen contributes a balanced account which is historical in approach and very readable; and W. A. Krehl's article on the nicotinamide-tryptophane relationships will help many people to get that confusing story clear in their minds. The chemistry of 4 gonadotropic hormones has been discussed by Choh Hao Li, but this is a more difficult chapter and the nomenclature assigned to the hormones, I.C.S.H., F.S.H., P.M.S.G., and H.C.G. does not simplify the issue for the ordinary mind. Some of the articles—e.g., those on the infra-red spectrometry of the steroids and the one on the sterioisomeric provitamins A—are highly technical and will be useful only to a limited circle of experts. Into rather a different category come the

SUMMARY

Perforation of a duodenal ulcer 15 months after vagotomy is reported. Only two other cases have been traced and in both of these the perforation occurred within a month of the vagotomy. The remarkable feature of the present case was the lack of rigidity after perforation. Pain, however, was severe, and shock was profound.

My thanks are due to Mr. Ivor Lewis for permission to publish this case and for his criticism, and to Dr. D. Ferriman who referred the case for surgery.

CHLORAMPHENICOL IN WHOOPING-COUGH

REPORT ON 5 SEVERE CASES

James Macrae
M.D. Glasg., F.R.F.P.S., D.P.H.
RESIDENT PHYSICIAN, HAM GREEN HOSPITAL, BRISTOL

The care of small infants with whooping-cough has always been anxious work. The case-fatality is high under the age of 3 months, and moreover the pulmonary complications of whooping-cough in infancy often remain as a permanent disability and may shorten the patient's life.

When it was reported in July, 1949, that chloramphenicol was active against *Hæmophilus pertussis* in vitro and in experimentally infected animals, a small stock of the drug was obtained and set aside for the treatment of infants with severe whooping-cough.

Since then, five infants have been so treated. The cases were selected as being severely ill, with a poor prognosis, but at a relatively early stage of the disease before secondary infections had been added. There was no clinical doubt of the diagnosis, which is sometimes difficult in small infants, and there was clear-cut evidence of direct contact with other cases of whooping-cough in every case.

The dosage, which was necessarily rather guesswork, was based on a minimum of 50 mg. per kg. of body-weight daily, with a generous increase in view of the severity of the infection and the low toxicity of the drug. Each baby received 0·25 g. as a first dose and thereafter 0·125 g. 6-hourly for 7 days and 0·125 g. 12-hourly for a further 7 days. It may be that these doses can be reduced as more experience is gained.

Administration of the drug was not difficult. The capsules were opened and the unprotected powder given by mouth in a little black-currant juice ('Ribena') by teaspoon some minutes before a feed. It was rather surprising to see this bitter-tasting drug go down so easily.

All the infants were nursed in complete isolation throughout the illness. The feeds the baby had been accustomed to before infection were continued, and replacement feeds with, if necessary, replacement doses of chloramphenicol were given to allow for vomiting. Careful records were made of coughing spasms and vomiting. No other drugs were given.

The details of the five cases are summarised in the accompanying table. The consistent gains in weight are remarkable considering how ill the infants were at the start of treatment.

Case 1.—This infant was badly cyanosed on admission and was having almost continuous ineffective spasms of coughing intermingled with tiny vomits. She was given oxygen without great effect for 24 hours. Great improvement was noted 12 hours after chloramphenicol was started, and general recovery was complete in 48 hours. Thereafter coughing spasms were short-lived and mild.

This child's life was despaired of by her mother and her recovery was regarded as a miracle by the parents. Even the more knowledgeable and disinterested nursing staff regarded the recovery of this first case as very remarkable.

Case 2.—Though not so severely ill as case 1, this little boy was cyanosed and exhausted from prolonged coughing spasms. His general recovery was well marked 24 hours after chloramphenicol was started, and after the 3rd day his coughing spasms became innocuous.

Case 3.—This little boy was as severely ill as case 1 and his recovery was equally dramatic, being complete in 24 hours.

Cases 4 and 5 ran a very similar course. Initially the exhausting, very protracted, coughing spasms were obviously useless and becoming more distressing each time. Some cyanosis was constantly present and the infants had become terrified of feeds because they brought on spasms of coughing. After 12 hours of chloramphenicol a remarkable repose was noted, and though coughing continued for a time it was obviously no longer a terrifying experience.

SUMMARY

Five infants severely ill with whooping-cough were treated with chloramphenicol. There was an immediate improvement in general condition in all the cases, followed by rapid recovery.

This somewhat preliminary report is submitted because of (*a*) the undoubted severity of infection in each case; (*b*) the dramatic recovery following chloramphenicol; and (*c*) lack of the drug to treat a larger series.

THE LANCET

LONDON: SATURDAY, MARCH 4, 1950

Function of the Regional Hospital Boards

As the months pass and the conflicts over the National Health Service Act subside, we see more clearly the size of the task entrusted to the regional hospital boards. Here and there in the counties people are beginning to ask not only what are the prospects of getting the funds for long-deferred improvements and extensions, but also more searching questions. Does the regional board really grasp the relative need of this or that ? Is not the allocation of funds sometimes decided by the eloquence of a management committee's spokesman rather than by reference to the region's master plan ? Indeed, might it not really be preferable, in the long run, if management committees were to deal direct with the Ministry rather than go through so tedious and uncertain a process as committing their projects to a regional board ?

Many have wondered whether the Act did not press the regional idea too far when it loaded one duty after another on the regional boards. Behind the vague and comprehensive phraseology of the Act dealing with the boards—" for the purposes of exercising functions with respect to the administration of Hospitals and specialist services in these areas "—one can discern four main responsibilities which they are expected to bear. First, there is the planning of hospital services in large areas, adumbrated in the Dawson report of 1920 and revived in the Sankey report of 1937. The need for grouping has been partly met by establishment of the hospital management committees, but the region has been left with much to arrange, involving attention to the shifting stresses and strains of modern society, such as the movement of populations and their tendency to grow older. Closely allied with this was a second idea—the integration of medical work in the hospitals throughout an area, the raising of standards in backward hospitals (as in the emergency services during the war), and the spread of influence from the universities. Before ever the nationalisation of the hospitals was mooted these first two functions of a possible regional body were already being vigorously discussed, and informed opinion was well-nigh unanimously behind them. The third and fourth functions—administration and financial control—fall into a different category, however, because they were called into existence only when the Bill was prepared. Under the Act, the regional boards, as the Minister's agents, became in theory responsible for the hospital and specialist services in the region: nominally, they appoint the staff and maintain the premises and equipment. Hence it follows that, within the limits laid down by the Ministry, they are responsible for settling all sorts of administrative questions and policies, answering queries, and giving advice over a vast range of topics. With this in turn is intertwined their financial responsibility. It was intended that they should have the greatest degree of financial autonomy consistent with the safeguards required in connection with public money: in other words, they were to have block grants and to manage their own affairs.

How far are the regional boards achieving success in these four functions ? The original emphasis on planning as the correction of the haphazard distribution of physical facilities has been pushed somewhat into the background, partly by the exigencies of the times, but partly also, one may suggest, by preoccupation with other issues and inadequate recognition of the need for staff free to settle down and concentrate on the job. It is fairly easy to arrange in a rough order of priority the schemes for capital developments submitted by the different hospital management committees, and to christen this the regional plan. But, though such a plan is much better than none at all, it falls short of what is needed. Planning, if it is to be business-like, must be based on accurate data: it must imply the use of existing resources to full capacity, and there must be a ceaseless study of comparative statistics. A great deal of work remains to be done, for even the current statistics of bed occupancy are unreliable: indeed, it is probably fair to say that we have not yet even formed a clear conception of what " planning " ought to mean in respect of hospital facilities over a large area. Secondly, the original emphasis on raising of standards—and especially medical standards—seems to be in some danger of getting lost in preoccupation with the grading of specialists and their remuneration. It is not, at present, apparent just how much further progress is to be made in the spread of university influence, except by the slow process of university participation in the appointment of consultants as vacancies occur from time to time throughout the region. This too is certainly something, but it falls short of the enthusiastic proposals current five or six years ago whereby able young men from the medical schools were to be sent out as registrars to establish and maintain new and better standards in the hospitals far distant from the medical schools. It falls short too of what is being done under the Bingham plan in Massachusetts with the aid of the Commonwealth Fund, and one is tempted to ask how many regions have found time to study these isolated but pregnant American experiments.

It is, however, the discharge by the regional hospital boards of the third and fourth functions that is causing the most heartburning. The idea that administrative responsibility for the hospital and specialist services would be vested in the region was never fully realised. On the one hand, by the time the Act was finally passed, much of this responsibility had been handed on to the hospital management committees. On the other hand, the passing of the Act was not accompanied by any sufficiently drastic overhaul of the machinery at Whitehall to ensure that circulars, or other decisions, did not by-pass or overrule the regional hospital boards. The boards thus received the insignia of administrative authority without the substance, and a certain amount of friction and confusion has followed. This is exemplified by the uncertainty surrounding the responsibility of the hospital management committee for its own medical staff, and may be summarised by saying that nominal articles on the vitamin requirements of the growing rat and of the guineapig, which have a value for all interested in the health of their laboratory animals.

It is difficult to see just why C. M. McCay's article on diet and ageing should have found a place in this volume. It contains little about vitamins or hormones and it might have found a wider circle of readers elsewhere. R. L. Stehle's section on the action of the post-pituitary hormones is rather disappointing: the historical approach is often helpful, but here undue prominence seems to have been assigned to older work, and not enough to the action of the antidiuretic hormone in the light of modern renal physiology. None of E. B. Verney's work since 1929 receives any recognition at all; the last of H. Heller's papers to be mentioned was published over ten years ago.

Despite this criticism, the volume as a whole is certainly as good as its predecessors, and it can be recommended to all those who have interests in these fields.

Finding the Missing Link

R. BROOM, D.SC., LL.D., F.R.S. London: Watts. 1950. Pp. 104. 6s.

DR. Robert Broom originally took up the cudgels on behalf of Prof. Raymond Dart, discoverer of *Australopithecus africanus* in South Africa in 1925, before giving up his medical practice and digging in this same field himself. After a couple of chapters on early forms of man he puts the case for the ape-man status of *A. africanus* extremely well, even polemically, not merely from the appearance of the Taungs skull but also from the indirect evidence of the associated fauna, which, he points out, was in all probability the remains of the meals of *A. africanus* and slain with sticks or stones. Next follows a thrilling account of Dr. Broom's own discoveries of further interesting hominoids in South Africa. Altogether he distinguishes four new species, belonging to three new genera: *Plesianthropus transvaalensis* found at Sterkfontein in 1936; *Paranthropus robustus* found at Kromdraai in 1938; and *Paranthropus crassidens* and *Telanthropus capensis* found at Swartkrans in 1948 and 1949 respectively. A description is also given of *Australopithecus prometheus* discovered at Makapan by other workers. Dr. Broom made his valuable finds in spite of the fact that the Historical Monuments Commission did all it could to stop him from excavating, and actually succeeded for a while, until General Smuts came to his rescue. The descriptive part of the book is followed by a discussion about whether these fossils are of men or apes. Dr. Broom prefers to call them ape-men, though he tells us that Prof. W. E. Le Gros Clark "now thinks they are human." This little book would be much more convincing if it did not attack English anthropologists for their caution in not accepting Professor Dart's and Dr. Broom's claims immediately.

The Temporal Bone and the Ear

THEODORE H. BAST, A.B., PH.D., professor of anatomy, University of Wisconsin; BARRY J. ANSON, M.A., PH.D., professor of anatomy, Northwestern University, Chicago. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1949. Pp. 498. 60s.

THIS book is the collected and documented account of researches carried out by the authors for over twenty years. The bulk of the work has already been published in numerous papers in various periodicals, and is here presented as a unified whole. The method adopted throughout was morphological—the study of numerous series of sections of many temporal bones of different ages. Photomicrographs, reconstruction models, and projection tracings of sections were the means used in analysing and synthesising the material. The authors suggest that a new terminology should be introduced in describing the structures of the labyrinth which more accurately fits their development. The special value of the research lies in the significance given to two fissures in the labyrinth anterior and posterior to the oval window. These fissures may retain an unstable embryonic structure into adult life and may become the site of aberrant cartilage and new bone formation. The relation of this process to the pathogenesis of otosclerosis is of great importance. In other parts of the book the development of the ossicles and air-cells is described: there is a special description of those cells in the petrous portion of the bone. The final chapter is an excellent historical summary of the theories of inner-ear function, with numerous well-selected quotations from the original accounts. The work is of high scientific quality, and beautifully printed and illustrated.

Colours and How We See Them

H. HARTRIDGE, M.A., M.D., SC.D., F.R.S., director of the vision research unit, Medical Research Council; professor of physic, Gresham College. London: G. Bell & Sons. 1949. Pp. 158. 15s.

Professor Hartridge gave these Christmas lectures at the Royal Institution in 1946. The many ingenious and striking demonstrations which he introduced then have been replaced in the book by some coloured plates and black-and-white diagrams, and in most cases by detailed descriptions of how they were contrived. This device is not very satisfactory, since it makes the book suitable neither for the children to whom the lectures were addressed nor for those who may wish to repeat the demonstrations. The exposition shows evidence of a similar conflict, being sometimes extremely elementary, and at others pretty advanced. Nor does there seem to be any underlying scheme to hold the arguments together: for instance, a good deal of elementary visual physiology is included which has no bearing on colour-vision. Moreover many of the views given here as facts are controversial: and this, surely, should have been indicated. The lectures themselves, with their demonstrations, must have been very good entertainment, but the book does not do them justice.

What is Psycho-analysis?

ERNEST JONES, M.D. London: Allen & Unwin. 1949. Pp. 126. 7s. 6d.

TWENTY years ago Dr. Jones drafted this book, and he has left it substantially as it was, with an addendum in which he summarises some changes, such as those Melanie Klein has introduced into the Freudian corpus. The account shows the clarity attained through mastery of a most complex subject. In his final remarks Dr. Jones rejects the half-hearted adherents whom his book might otherwise persuade: he says that we are impelled to conclude that either the findings of psycho-analysis are untrue or else they are of momentous import, but it is certain that they are not half-true. Non-analysts, even after reading this book, will hesitate to believe all Freud's findings wholly true, though they may not wish to insist that the fraction should be a half.

Problems of Bisexuality as Reflected in Circumcision (London: Imago Publishing Co. 1949. Pp. 83. 10s.).—In this article, reprinted from the *International Journal of Psycho-analysis*, where it appeared in 1947, Dr. Herman Nunberg maintains that circumcision represents submission to the will of the father, an essentially homosexual relationship: since it also activates masculine aims, according to Dr. Nunberg, it produces a conflict which can lead to the creation of myths and religious systems. Based on the psycho-analysis of a very small number of patients, the material presented is not likely to convince theologians or anthropologists.

The Chemical Analysis of Foods (4th ed. London: J. & A. Churchill. 1950. Pp. 340. 28s.).—It is only four years since the third edition of this book by Mr. Henry Edward Cox, D.SC., appeared, and everyone who has used that edition will hasten to buy the fourth. There are new data about baking-powders, vinegars, soya meal, onions, meat extracts, sausages, tomatoes, ketchups, and egg products; moreover, the numerous orders or standards issued by the Ministry of Food have been sorted out, and those likely to be of permanent value are included. The methods of analysis are clear and foolproof and there is enough comment to make the reasons for the different steps of the techniques apparent. Sometimes the comment strays into the realm of nutritional science—for example, "the pulse proteins have peculiarly high biological value"; which is unfortunately not true. A reading of this book with an eye to adulteration of foods throws an unpleasant light on unrestricted individual initiative in the food industry.

THE LANCET

LONDON: SATURDAY, MARCH 4, 1950

Function of the Regional Hospital Boards

As the months pass and the conflicts over the National Health Service Act subside, we see more clearly the size of the task entrusted to the regional hospital boards. Here and there in the counties people are beginning to ask not only what are the prospects of getting the funds for long-deferred improvements and extensions, but also more searching questions. Does the regional board really grasp the relative need of this or that ? Is not the allocation of funds sometimes decided by the eloquence of a management committee's spokesman rather than by reference to the region's master plan ? Indeed, might it not really be preferable, in the long run, if management committees were to deal direct with the Ministry rather than go through so tedious and uncertain a process as committing their projects to a regional board ?

Many have wondered whether the Act did not press the regional idea too far when it loaded one duty after another on the regional boards. Behind the vague and comprehensive phraseology of the Act dealing with the boards—" for the purposes of exercising functions with respect to the administration of Hospitals and specialist services in these areas "—one can discern four main responsibilities which they are expected to bear. First, there is the planning of hospital services in large areas, adumbrated in the Dawson report of 1920 and revived in the Sankey report of 1937. The need for grouping has been partly met by establishment of the hospital management committees, but the region has been left with much to arrange, involving attention to the shifting stresses and strains of modern society, such as the movement of populations and their tendency to grow older. Closely allied with this was a second idea—the integration of medical work in the hospitals throughout an area, the raising of standards in backward hospitals (as in the emergency services during the war), and the spread of influence from the universities. Before ever the nationalisation of the hospitals was mooted these first two functions of a possible regional body were already being vigorously discussed, and informed opinion was well-nigh unanimously behind them. The third and fourth functions—administration and financial control—fall into a different category, however, because they were called into existence only when the Bill was prepared. Under the Act, the regional boards, as the Minister's agents, became in theory responsible for the hospital and specialist services in the region : nominally, they appoint the staff and maintain the premises and equipment. Hence it follows that, within the limits laid down by the Ministry, they are responsible for settling all sorts of administrative questions and policies, answering queries, and giving advice over a vast range of topics. With this in turn is intertwined their financial responsibility. It was intended that they should have the greatest degree of financial autonomy consistent with the safeguards required in connection with public money : in other words, they were to have block grants and to manage their own affairs.

How far are the regional boards achieving success in these four functions ? The original emphasis on planning as the correction of the haphazard distribution of physical facilities has been pushed somewhat into the background, partly by the exigencies of the times, but partly also, one may suggest, by preoccupation with other issues and inadequate recognition of the need for staff free to settle down and concentrate on the job. It is fairly easy to arrange in a rough order of priority the schemes for capital developments submitted by the different hospital management committees, and to christen this the regional plan. But, though such a plan is much better than none at all, it falls short of what is needed. Planning, if it is to be business-like, must be based on accurate data : it must imply the use of existing resources to full capacity, and there must be a ceaseless study of comparative statistics. A great deal of work remains to be done, for even the current statistics of bed occupancy are unreliable : indeed, it is probably fair to say that we have not yet even formed a clear conception of what " planning " ought to mean in respect of hospital facilities over a large area. Secondly, the original emphasis on raising of standards—and especially medical standards—seems to be in some danger of getting lost in preoccupation with the grading of specialists and their remuneration. It is not, at present, apparent just how much further progress is to be made in the spread of university influence, except by the slow process of university participation in the appointment of consultants as vacancies occur from time to time throughout the region. This too is certainly something, but it falls short of the enthusiastic proposals current five or six years ago whereby able young men from the medical schools were to be sent out as registrars to establish and maintain new and better standards in the hospitals far distant from the medical schools. It falls short too of what is being done under the Bingham plan in Massachusetts with the aid of the Commonwealth Fund, and one is tempted to ask how many regions have found time to study these isolated but pregnant American experiments.

It is, however, the discharge by the regional hospital boards of the third and fourth functions that is causing the most heartburning. The idea that administrative responsibility for the hospital and specialist services would be vested in the region was never fully realised. On the one hand, by the time the Act was finally passed, much of this responsibility had been handed on to the hospital management committees. On the other hand, the passing of the Act was not accompanied by any sufficiently drastic overhaul of the machinery at Whitehall to ensure that circulars, or other decisions, did not by-pass or overrule the regional hospital boards. The boards thus received the insignia of administrative authority without the substance, and a certain amount of friction and confusion has followed. This is exemplified by the uncertainty surrounding the responsibility of the hospital management committee for its own medical staff, and may be summarised by saying that nominal authority often rests with the regional board, but local knowledge and hospital experience mean that the hospital management committee must in practice have the last word. As to the financial responsibility, the failure so far to devise any system which would enable the Ministry to make block grants has produced a series of shocks to the confidence of the hospital management committees, and has more than any other single factor weakened the position of the regional hospital boards. They have to face both ways—to ask the Ministry for more, and to tell the hospital management committees to do with less—and it is therefore hard for them to gain the committees' confidence. Praiseworthy efforts are now being made in a number of places to develop costing systems which will permit of the rational calculation of block grants; and success here might well transform the whole scene by making possible real delegation of financial, and subsequently administrative, responsibility. Success here would also—if this were thought desirable—permit of a direct relationship between the hospital management committees and the Ministry in regard to maintenance finance; but the Ministry's decision to delegate final approval of management committees' estimates to the regional boards (see p. 426) indicates that it wishes to strengthen their hand rather than circumvent them.

The line of argument we have followed suggests that there is a good deal to be said for concentrating the efforts of the regional boards on the planning of physical facilities in the broad sense, and on the raising of standards of diagnosis and treatment. If the various administrative responsibilities could be clarified it may be that we could go further and relieve them of many of the somewhat fictitious responsibilities they now carry in regard to administration. But it cannot be pretended that the discussions on these large matters have yet been carried far enough to justify any sweeping conclusions on the ways in which the work of the boards can best develop.

Choice of Weapons against Infections

FOR the time being chloramphenicol and 'Aureomycin' are distributed only through regional centres for use in a limited range of infections which do not respond to penicillin or streptomycin. But it may not be long before the restrictions are removed from chloramphenicol, since it is being made synthetically in England in increasing quantities; and if the dollars can be found no doubt aureomycin will follow suit. The clinician will then have the various sulphonamides and four powerful antibiotics to choose from when treating bacterial diseases. How should he make his choice? Therapeutic effectiveness and low toxicity are obviously the first considerations, but ease of administration and cost may also have to be thought of when treating the less severe infections. Ideally the causal organism and its drug sensitivities should be determined in every case before treatment is begun. But this takes time, and the clinicopathological studies of the last few years have made clinical diagnosis much more precise as regards the flora likely to be found in a given case. Nevertheless, an exact bacteriological diagnosis is always desirable in severe infections and those not responding to treatment as expected, for the bacteriologist can guide the clinician not only in choice of drug but also in the dosage required.

There has so far been little opportunity in this country to compare the range, activity, and toxicity of aureomycin and chloramphenicol with those of the other antibiotics and the sulphonamides. Controlled clinical trials in specific infections are badly needed, but meanwhile we can learn something from the American experience. The accompanying table is based on the recommendations of Prof. PERRIN H LONG and his colleagues,[1] with a column added to show which of these common infections responds to the sulphonamides.

Infecting organism	Order of preference of antibiotics				Response to sulphonamides
	Penicillin G	Streptomycin	Aureomycin	Chloramphenicol	
Group A streptococcus	1	3	2	—	+
Group D streptococcus	2	—	1	—	0
α Hæmolytic streptococcus	1	2	2	—	±
Staphylococcus ..	1	—	2	—	+
Pneumococcus ..	1	3	2	—	+
Meningococcus ..	1	—	—	—	+
Gonococcus	1	2	3	3	+
Brucella abortus ..	—	—	1	1	±
H. pertussis	—	—	2	1	0
H. influenzæ	—	2(+ Sd)	1(+ Sd)	—	+
B. anthracis	1(+ Sd)	—	—	—	+
S. typhi	—	—	2	1	0
Salmonella-shigella group .. .	—	—	—	1	+
Bact. coli ..	—	2	1	1	±
Proteus vulgaris ..	—	2	—	1	0
Ps. pyocyanea	—	1	—	2	0
Tr. pallidum	1	—	2	—	0

1, 2, and 3: 1st, 2nd, and 3rd choice. —: inactive or insufficient evidence of value. Sd: sulphadiazine. +, ±, and 0: good, partial or variable, and no response.

This table at best represents only current practice; for some of the recommendations there is still little detailed evidence, and the newer antibiotics are still untried in a great many less common infections In some diseases the choice is fairly obvious: in typhoid, for instance, chloramphenicol seems to be far more active than any other known drug, with the possible exception of aureomycin. In some infections there is little to choose between two or more drugs Thus against the meningococcus, penicillin and sulphonamides (given intravenously) are both highly effective. The real difficulty arises with the everyday coccal and coliform infections. The mention of a staphylococcal infection immediately brings to mind the use of penicillin, or streptomycin, if the strain is penicillin-resistant. Now, however, Professor LONG tells us in his letter on p. 420 that the drug of choice is aureomycin, to which the staphylococcus has so far not become resistant. But it should not be forgotten that sulphathiazole and sulphadiazine are both effective against penicillin-fast staphylococci, and for local application so is dibromopropamidine. Against other cocci there is at first sight little that the antibiotics can do that the sulphonamides cannot do equally well. And in ordinary streptococcal infections, such as tonsillitis, sulphanilamide is still one of the best remedies. Where a streptococcal or pneumococcal infection is exceptionally acute the neutral salts of sulphonamides for injection are useful to ensure a rapid therapeutic concentration in the blood. Against the coliform organisms streptomycin must be placed

below aureomycin and chloramphenicol and perhaps below the sulphonamides also, because of the readiness with which these organisms become streptomycin-fast. This fastness is particularly common in urinary infections, and in these the sulphonamides are probably the drugs of choice, at any rate while the new antibiotics are scarce. Bacillary infections of the gut, other than the typhoid group, respond fairly well to the less soluble sulphonamides such as phthalylsulphathiazole and succinylsulphathiazole. Gonococcal infections are perhaps best treated with penicillin; but thousands of cases, particularly in the East, will still be treated with sulphonamides because of their convenience and cheapness.

The side-effects of the sulphonamides have been considerably reduced by improvements in the technique of administration and the introduction of new compounds; but penicillin still leads the field in freedom from toxicity, its only serious side-effect being skin eruptions due to acquired sensitivity. The most toxic of the drugs we are considering is undoubtedly streptomycin, with its tendency to produce rashes and damage to the eighth nerve when it is given for more than a very short period. The new drugs both produce gastro-intestinal upsets, and chloramphenicol has some curious effect on the muscles of accommodation; it cannot yet be said that all the unwanted effects of aureomycin and chloramphenicol are known.

Both aureomycin and chloramphenicol are fully active by mouth, as, of course, are the sulphonamides. Penicillin, on the other hand, must be given in much larger doses by mouth to get the same blood-level as by injection; and the level produced is not always reliable. In a long-lasting infection it is to everybody's advantage if injections can be avoided, as they usually can, at any rate after the first few days, in sulphonamide therapy. However, the objection to penicillin that frequent intramuscular injections are needed has largely been overcome by the introduction of the slowly absorbed preparations; with procaine penicillin in oil plus aluminium monostearate the injections can be cut down to one a day or even one in several days. When streptomycin is given by mouth the blood-levels obtained are insufficient for the treatment of systemic infections, but there is a startling effect on the flora of the bowel. The coliform organisms are almost entirely eliminated, and something approaching bacteriological sterility of the fæces may be found. The same sterilising effect is produced by chloramphenicol by mouth, though it also produces a therapeutic blood-level. The poorly absorbed sulphonamides are widely used for their effect on the bowel organisms, and it is not always remembered that sulphaguanidine produces a considerable blood-level as well. It comes to this therefore: the sulphonamides, aureomycin, and chloramphenicol will be given by mouth unless an exceptionally rapid effect is required, when injection will be preferred. Streptomycin will be injected unless the aim is to sterilise the bowel. Penicillin will usually be injected but when an exact blood-level is not important and the patient is a child or there is some other reason for avoiding injections it may be given by mouth in four to five times the dosage. As regards cost, there seems to be little to choose between penicillin and sulphonamides in the everyday case, but special preparations, such as the "depot" penicillins (but not the neutral injectable sulphonamides), are somewhat more costly. Streptomycin is much cheaper than it was, but still dearer than either of these two. The cost of the new antibiotics can hardly be considered while their present scarcity continues.

PERRIN LONG and his colleagues suggest that a combination of drugs should be used more often in severe infections. Thus in subacute bacterial endocarditis they advocate a combination of penicillin, streptomycin, and aureomycin if the organism is a gram-positive coccus, whereas if it is a gram-negative bacillus they replace the penicillin by chloramphenicol. In anthrax and *H. influenzæ* infections they give sulphadiazine plus an antibiotic. The purpose behind these combined operations is to attack the micro-organism's metabolic cycle from different directions or at more than one point. Sometimes, too, a combination reduces the risk of the organism becoming drug-fast, the most firmly established example of this effect being the use of streptomycin plus *p*-aminosalicylic acid in tuberculosis. A mixture of sulphonamides is now known to give better results than a single drug in some infections, besides reducing the incidence of crystalluria. The potentialities of combined therapy certainly deserve to be explored further, but it will be a pity if the blunderbuss returns to fashion against infections which will always succumb to a single well-directed bullet.

Multiple Primary Tumours

ARE people who have had a malignant tumour successfully removed more likely or less likely than other people to get a new primary growth? In other words, has the cancer patient an immunity or a heightened susceptibility to further cancer? There is no plain answer to this plain question.

Multiple tumours are of two main classes: (1) multiple similar tumours arising from the same kind of tissue, and (2) multiple dissimilar tumours arising from different tissues. Examples of the first class are multiple carcinomas of the large intestine (e.g., in polyposis), multiple basal-cell or squamous-cell cancers of the skin, bilateral carcinomas of the breast, ovaries, or other paired organs, bilateral retinoblastoma, and the multiple osteogenic sarcomas arising in men or animals after exposure to radioactivity. In all of these cases a more or less extensive field of similar tissue has been exposed to similar agents, the tumours which appear are the result of multifocal cancerous change—simultaneous or successive—in this prepared field, and there is nothing surprising in the fact that the incidence of multiplicity greatly exceeds that due to mere chance. The reported incidence of multiple dissimilar tumours vary widely. Some statistical analyses seem to show that they are more common than would be expected by chance, whereas others seem to show the reverse. But these analyses are all unsatisfactory because they are based on inaccurate estimates of the frequency of the individual kinds of tumours If we knew the true incidences of, say, cancer of the stomach and cancer of the lung in a whole community, or in any specified age-group or other section of it, we could estimate how often those two tumours would be associated by chance in that community or group and compare the result with the observed frequency. But for the great majority of dissimilar primary tumours the data are not accurate enough to make this possible.

There are many other difficulties and fallacies in this field. As "benign" and "malignant" are only relative terms and do not denote sharply distinct classes of tumours, all neoplasms, whether benign or malignant, should strictly be included in an analysis of the incidence of multiple primary growths; yet this is seldom done. If we confine our attention to "malignant" tumours only, we must specify precisely what tumours we regard as malignant. Among gliomas, mixed salivary tumours, basal-cell growths of the skin, osteoclastomas, ganglioneuromas, teratomas, and papillary growths of the breast, intestine, and urinary tract, the distinction between innocence and malignancy is highly arbitrary. Shall we include all members of these classes in our analysis of multiplicity, or only those which show unquestionable evidence of malignancy? Clearly also, how often multiple primary growths are discovered will depend on the thoroughness of the search. Purely clinical studies will reveal far fewer examples than necropsies, and perfunctory necropsies will reveal fewer than thorough ones; thus, as we pointed out on Feb. 11 (p. 268), by cutting sections at 4 mm. intervals ANDREWS [1] has found carcinomas in 12% of prostates which gave no clinical or naked-eye signs of malignancy.

All these factors detract from the value of published series of multiple primary tumours.[2] If from these series we subtract the multiple similar tumours which have arisen in predisposed fields of similar tissue (a multiplicity which was to be expected) we are left with various coexisting dissimilar tumours, whose frequencies are wholly unreliable.

Annotations

ADMISSIONS TO HOSPITAL

INQUESTS at Ipswich and Hove have lately drawn attention to the difficulty of getting patients admitted to hospital. The Ipswich case arose out of the death of a baby who was admitted to hospital after a delay of $4\frac{1}{2}$ hours. It turned out that the delay probably had nothing to do with the child's death; but the fact remains that the child's doctor spent a good deal of time being passed from one official to another in various hospitals.

In July, 1948, the responsibility for admitting any given patient passed from the local hospital to the National Health Service in general; and in practice this may mean the hospital management committee or the regional board, according to whether the district is rural or urban. It is, therefore, most important that these authorities should have their own admission office which can take from the doctor the responsibility of finding a bed, thus releasing him from the tiresome business of ringing up a number of hospitals. Already such offices have been established by most of the regional boards and by many management committees; but in large areas there is still no such system and the responsibility for securing patients' admission lies solely with the general practitioner.

The Hove case takes the problem a stage further, dealing with a patient who had been put on the waiting-list owing to lack of accommodation, and who died while still waiting. Until many more beds are available, waiting-lists of chronic sick are inevitable; but it seems that tragedies could be averted if every case were visited by a doctor from the management committee, in order to ensure strict medical priority. Such a system already operates in the St. Helier group, where it has not only ensured that urgent cases get in first, but also that cases found not really to need admission are looked after by the various domiciliary agencies. There is nothing mysterious about this valuable scheme, which could, it seems, be reproduced elsewhere with equally good effect.

MEN, FOOD, AND CIVILISATION

How many more of us can this distracted globe maintain? This is not a question which appeals deeply to enthusiasts for a higher birth-rate, who are apt, indeed, to look another way when it is raised. But as Dr. A. S. Parkes, F.R.S., remarked in his Galton lecture [1] (ominously entitled The Primrose Path), food-supplies are increasing barely as fast as population; so, unless great efforts are made, present standards of living will not even be maintained, let alone improved.

Population trends in Great Britain, thanks to the report of the Royal Commission on Population,[2] are now well known. We are increasing in numbers and will most likely go on increasing for another twenty-five years; we are ageing, as a population, but also living longer, and we muster about 49 million. The world population is thought to be about 2000 million, and "short of some major upheaval it seems likely that the human race will continue to increase in total numbers." Even during the course of Dr. Parkes's lecture, as he fairly warned his hearers, it had increased by some 3000; in the same time the average age had risen, and the inborn quality, he thought, had very likely declined. We might well be settling down to thinking how we are going to feed this prospective society of decadent greybeards; but our most active research on a large scale at the moment has to do with atomic warfare. A cynic might suppose that this offered one answer to the population problem, but as Dr. Parkes pointed out, modern warfare is a failure from this point of view. "The military technician has latterly made killing so inefficient in relation to effort, and so expensive in relation to resources, as to be almost prohibitive. The number of man-hours required and the average cost of killing a combatant by military means in the last war must have been quite fantastic." There seems to be a hint of good news in this for somebody: the ordinary civilian, perhaps—unless civilians are cheaper to kill than combatants. At least it raises the hope that somebody, some day, will say, "My dear fellow, I simply can't afford to kill you." Of course atomic warfare might well thin the population in one generation by rendering large numbers of males sterile. But even this difficulty might be overcome, Dr. Parkes hinted: recent research suggests that it may soon be possible to store the spermatozoa of animals in such a way that they will survive in a functional state for years.

He took the somewhat old-fashioned view that war, even if not particularly destructive of mankind, is at all events dysgenic, since it removes selectively young virile males. Apart from the fact that this form of selection no longer holds in modern warfare, there is some evidence that even in the old days, when civilians were less exposed to assault, the effects of war on the race were hardly perceptible. Raymond Pearl [3] estimated

that after the 1914–18 war the loss to the American race was only 0·055% of the 1910 population and 0·048% of the 1920 population: and he thought it unlikely that any geneticists would regard 5 hundredths of 1% as a significant loss from the gene-pool of the race. Even the figure for France in that war—which Pearl put somewhere between 1·3 and 3·4% of the population—could have had no measurable effect on the quality of the race. The survivors came home in the prime of manhood and no doubt most of them founded families. Dr. Parkes himself quoted the findings of Dr. Richardson that deaths from "fatal quarrels" in the world, between 1820 and 1945, only accounted for 1·6% of the total death-rate; and he included under the heading of fatal quarrels everything from murders to world wars—an example, Dr. Parkes said, of the broad flexible outlook. Murderers came second to world wars in their contribution; small wars were, relatively speaking, nowhere. Senility does not account for a very large proportion of deaths, and pestilences are steadily declining in killing power under the assault of medicine.

The impression is left of a virtually immortal species looking round for something to eat. Taking the long view, surely now is the time to start cultivating our gardens, and that in a big way.

TRAINING FOR THE HEALTH SERVICES

Throughout the world, and especially in Africa, Asia, and the rural areas of Europe and America, the shortage of doctors and other health workers is a grave problem: and from Feb. 6 to 11 an expert committee, called together by the World Health Organisation, discussed in Geneva what could be done to improve professional and technical education, in both advanced and underdeveloped countries. The rôle of the doctor in modern society, the committee pointed out, has changed remarkably within a generation. His clinical responsibility has been broadened by his increasing sense of the importance of the background of his patients, including social and economic conditions, nutrition, industrial health, and the whole environment of home and family. For this if no other reason the undergraduate medical curriculum has in most areas lost its balance. Almost everyone admits that outworn disciplines remain while countless new subjects jostle with one another for a place in the disordered course of study; but the real fault lies deeper—in the failure of training to keep abreast of social and industrial progress. A drastic revision of the curriculum *as a whole* is necessary, not merely a readjustment of the parts.

One of the essential tasks of W.H.O. is to lay down basic standards of training for the practice of public health, but this cannot be even attempted until undergraduate education has been reshaped. Social medicine, the committee agreed, is not simply another "subject" introduced into the curriculum: on the contrary it is a way of thinking and teaching which should aim at giving the student a new outlook on all his subjects. When the teaching of social medicine has been given its proper place, and its practice has been established in the clinical studies generally, we shall be able for the first time to set out a design for postgraduate education in public health.

In the committee's view the medically qualified health officer, the sanitary engineer, and the public-health nurse should learn to work together, and to understand one another's points of view, during the training period. In this way they will carry the team spirit into their work in any part of the world. The committee recommended various ways and means of meeting the shortage of health workers, above all by making the best and most economical use of the more highly trained staff. This demands greater care in the selection and training of auxiliary staff, especially in countries where the doctors and fully trained nurses are lone figures among a huge mass of people. W.H.O.'s programme in this field includes plans for assisting countries to develop their own medical schools and other teaching institutions, for organising group training for health workers at various levels, and for the training of local personnel by demonstration teams. The committee gave their blessing to these plans, and also to schemes for awarding fellowships to senior teaching staff, and for providing experts to develop teaching methods in the regions themselves, against the background of local conditions.

Unesco will continue to coöperate with W.H.O. on training and scientific exchange, and plans are being made for further collaboration in the technical assistance programme for under-developed countries.

DANGER FROM THE NEWER INSECTICIDES

Powerful new insecticides are now on sale which are from three to five times as toxic as nicotine. They will shortly be in use in greenhouses, orchards, and fields, and it is as well that practising doctors should be aware of the hazards they present alike to the agricultural worker and the householder. They contain organic compounds of phosphorus and they are as dangerous to man and domestic animals as to the creatures they are intended to destroy. In factories protective measures can be successfully applied to prevent poisoning, but in the field the difficulties in ensuring adequate protection for individual workmen are almost insurmountable. Poisoning may be caused either by the accidental ingestion of vegetation containing systemic insecticide[1]—a risk perhaps more likely to affect animals than man—or by direct contact with the chemical during preparation or application. Some months ago Dr. James Wilson,[2] secretary of the American Medical Association's council on pharmacy, urged that the public should be protected against some of the newer insecticides; and this warning was powerfully reinforced on Nov. 15 by Dr. Donald Hunter at the end of his Ernestine Henry lecture to the Royal College of Physicians.*

Dr. Hunter was speaking particularly about the organic phosphorus compounds, of which 'Parathion' (diethyl - *para* - nitrophenylthiophosphate) is a good example. These compounds, discovered in Germany in 1939, were put into production in the United States and Britain soon after the end of the war and are now being widely used as sprays in agriculture. Liquid preparations, wettable powders, and dusts containing parathion are already in use; and smoke canisters containing it are being tested for the fumigation of enclosed spaces. The organic phosphorus insecticides are alkylpolyphosphates resembling di-isopropyl fluorophosphonate (D.F.P.) They are extremely poisonous. All preparations readily penetrate the skin and exposure to no more than 0·3 g. a day may be fatal; absorption also follows inhalation and ingestion. At first the victim complains of giddiness and possibly headache, aggravated by eating or smoking; and the pupils are usually constricted to pin-point size. Then follow gastro-intestinal symptoms, muscular twitching, coma, convulsions, pulmonary œdema, and commonly incontinence of urine and fæces. In fatal cases death may occur an hour or two after the onset of symptoms. Atropine is the antitode to parathion. Large doses—up to gr. $^1/_{30}$ hourly—must be given. For pulmonary œdema oxygen should be administered early and under slight pressure to overcome bronchial spasm. Where fibrillary twitching of muscles affects particularly the diaphragm, artificial respiration is necessary to save life.

In factories where parathion is manufactured the precautions should include conditions assuring its absence from the atmosphere; protective clothing should be worn (all clothes, including underwear, being laundered after one day's wear), and respirators should be at hand for use in emergency. In the field, respirators must be worn during dusting and during the diluting of wettable powders containing parathion. Hitherto there seem to have been no serious mishaps in Great Britain; but Dr. Hunter's account of the accidents in the U.S.A. and elsewhere made it clear that the strictest precautions are indispensable if casualties are to be avoided. Moreover, every practitioner and casualty officer must be ready to recognise the symptoms and signs for what they are, so that the right treatment shall be given immediately.

REPORT ON NUTRITION

In 1933 the British Medical Association appointed a committee "to determine the minimum weekly expenditure on foodstuffs which must be incurred by families of varying size if health and working capacity are to be maintained, and to construct specimen diets." The committee assumed in its report[1] that to maintain health and working capacity the normal man of average stature required 3400 calories daily in the food as purchased; and it suggested that these should be derived from 100 g. of protein (half of which should be first-class), 100 g. of fat (of animal origin as far as possible), and 500 g. of carbohydrate. On this basis a scale of man-value calorie coefficients was drawn up, and sixteen specimen diets were constructed and costed; the average daily cost of the "bare ration" for a normal man was about 4*s.* 10*d.* In constructing the diets the committee underlined the importance of sufficient milk for children, and of dairy produce, fruits, and green vegetables. The recommendation of 3400 calories appeared to conflict with that of an official committee of the Ministry of Health. In January, 1931, a nutrition advisory committee had been appointed as a permanent body to "advise the Minister of Health on the practical application of modern advances in the knowledge of nutrition." In a memorandum, entitled "the Criticism and Improvement of Diets," the committee maintained that 3000 calories and 37 g. of first-class protein was enough for the average "man" of the entire population. Since the two committees seemed to differ, a joint conference was held; it concluded[2] that there was no fundamental disagreement on matters of scientific fact.

In October, 1947, the council of the British Medical Association again appointed a special committee "to examine the whole question of nutrition in this country and prepare an authoritative report with particular reference to the adequacy or inadequacy of the wartime and post-war diet." The committee's report is issued this week.[3] This includes tables of nutritional allowances for the two sexes in different age-groups; and the age-groups and most of the nutritional allowances adopted are those which were used during the war by the Oxford Nutrition Survey and have lately been published.[4] This makes for a welcome uniformity, for there are already several scales of nutritional allowances: a new edition of the Recommended Dietary Allowances of the National Research Council was published in 1948,[5] and a new dietary standard has also been introduced for Canada.[6] The B.M.A., Oxford, and Canadian standards refer to the average person, but the National Research Council standards are "levels enough higher to cover substantially all individual variations in the requirements of normal people." In general, the National Research Council standards are highest, with the B.M.A. next, the Oxford third, and the Canadian lowest. The greatest discrepancies come in ascorbic acid. For instance, in the age-group 0 through 1 year, the National Research Council allows 32 mg., the B.M.A. 10 mg., Oxford 10 mg., and Canada 30 mg.; for a moderately active man the respective figures are 75, 20, 30, and 30 mg; for a lactating woman they are 150, 50, 90, and 30 mg. The B.M.A. report does not give much evidence for the figures adopted, and some will not generally be accepted. For instance, the committee states that the energy derived from protein during the late war usually represented 10–14% of the total calories; and for adults (other than pregnant and nursing women) not engaged on hard work, the committee recommends that 11% of the total energy should be provided from protein. If there is no serious deficiency in the population this figure (which represents 87 g. of protein daily for a moderately active man) appears to be high; if it represents about the *average* intake in the population, half the population probably consume less and half more, yet there is no evidence that half get insufficient.

A comprehensive chapter on food-consumption levels includes unpublished figures of the Ministry of Food. The committee concludes that

> "since 1939 the diet of the nation has, on the average, deteriorated in variety and palatability, but that supplies of calories have been well maintained and those of most nutrients have increased. . . . Nevertheless, in spite of the large amounts of data which the Committee has considered, direct information about the consumption of food by different groups is disappointingly scanty and it is not possible to determine with any certainty what degree of underfeeding, if any, there has been in the population."

From the medical aspect, most interest will be found in the chapter on clinical assessment of the nation's health in terms of nutrition. Unfortunately the methods for this assessment are not simple, and the committee "urges that every effort be made to devise reliable methods of assessing by clinical (including anthropometric and biochemical) procedures the state of nutrition of the population." The evidence is considered under several headings. From statistics of mortality and morbidity it is concluded that "because of the complex nature of the many factors involved, it is not possible to say to what extent, if any, the wartime improvement in mortality rates has been due to changes in diet." Data on growth and development are scanty, and the committee regrets that the results of the body-weight survey by the Ministry of Food have not been published; data for children indicate that "physique was maintained or improved during the war years, with perhaps the exception of 1941, but tended to fall back in the years 1945–7." The results of purely clinical surveys are rapidly dismissed; and a number of biochemical results are given, including unpublished data of the Oxford Nutrition Survey. From all this emerges the cautious conclusion that "having regard to all the facts and data which have been before the Committee, it would appear to be a fair conclusion that the health of the population as a whole, despite the trials and tribulations of recent years, has been well maintained."

The main value of the report appears to lie in the marshalling of a number of scattered data relating to various aspects of nutrition, and in the interpretation of these data by the expert committee. The report emphasises over and over again the scantiness of the published data on the nutritional state of the country during and after the war. However, in due course the valuable and extensive data of the pre-war Aberdeen Carnegie Survey and of the war-time Oxford Nutrition Survey are to be issued in detail. The moral seems to

be that the work of those who are attempting by various means to assess the nation's nutrition should be more closely coördinated—and perhaps more keenly encouraged.

THE SYSTEMIC COLLAGENOSES

SEVERAL of the diseases which a few years ago were thought to affect the skin only are now known to be systemic diseases with dermal manifestations. Thus scleroderma, dermatomyositis, and lupus erythematosus were so called because to earlier clinicians they seemed to be essentially skin disorders. It is now apparent that they are better regarded as collagenoses—conditions involving the collagen of the blood-vessels, or of the connective and supporting tissues, or both. Morphœa, or localised scleroderma, usually seems to be confined to the skin, but the lesions may be multiple, and in 13 cases of linear scleroderma Rubin [1] found a high incidence of spina bifida occulta and other spinal abnormalities, suggesting a trophoneurotic ætiology. Generalised scleroderma usually begins either as Raynaud's phenomenon or the acrosclerosis of Sellei,[2] or as an acute febrile illness closely resembling and probably identical with dermatomyositis. In this issue, Dr. Church and Dr. Ellis report 2 cases of scleroderma with cystic pulmonary fibrosis, and they point out that it was D. W. Finlay, of Middlesex Hospital, in 1891, who first recognised that the lungs may be involved in generalised scleroderma; in fact, the lungs may be affected before the skin.[3] They describe similar histological changes in the lungs in disseminated lupus erythematosus, rheumatoid arthritis (which is sometimes associated with scleroderma), and polyarteritis nodosa. Besides the lungs, scleroderma may involve the connective tissue, heart, gastro-intestinal tract, kidneys, ductless glands, and eyes, and Goetz [4] therefore suggests that "progressive systemic sclerosis" would be a more suitable name for the disease, at least until its ætiology is established. Wainger and Lever [5] regard the muscular and collagenous degeneration of dermatomyositis as primary and the inflammation as secondary. Pagel and his colleagues,[6] from their histological observations, conclude that the changes in muscle, collagen, and blood-vessels are all non-specific, only differing from those found in disseminated lupus erythematosus in the additional involvement of muscle and the relative rarity of renal and endocardial lesions. When lupus erythematosus occurs in the so-called acute disseminated form—an unfortunate term because the condition is systemic rather than disseminated and severe rather than acute—it may be widespread on the surface but some of the worst cases have phases in which there are no active skin lesions but ample evidence of severe systemic involvement in albuminuria, leucopenia, a raised erythrocyte-sedimentation rate, and an inverted albumin-globulin ratio. McCreight and Montgomery [7] have found that collagenous and vascular degenerative changes in lupus erythematosus are much less common in the skin than in other organs, and from an analysis of 132 disseminated cases they concluded [8] that lupus erythematosus is not primarily a collagenous disease. Nevertheless, collagenous degeneration of the endocardium, and focal fibrinoid degeneration of the arterioles of the heart, liver, spleen, lymph-nodes, and other organs are often found [9] with "wire looping" of the glomerular capillaries which is probably also a fibrinoid degeneration.

Is there a common denominator in scleroderma, dermatomyositis, disseminated lupus erythematosus, and polyarteritis nodosa? Fox [10] suggested that disseminated lupus erythematosus may be the response to an antigen which persists in the body and is being continually applied. He described fatal lupus erythematosus after injections of anti-tetanus serum, and polyarteritis has been reported in relation to serum sickness and the administration of sulphonamides and other drugs, and also probably as a reaction to bacterial and parasitic antigens. Alexander and his co-workers [11] explained the unresponsiveness of human skin to weal-forming drugs for 48 hours after the first exposure by assuming that, once the intermediary H-substance is released from the dermal cells by such drugs, it takes 48 hours for this essential component of the defensive mechanism in the vessels to be built up again to the level of an effective urticarial reaction. Here perhaps lies the explanation of some of the dermal and vascular collagenoses. Dermatomyositis, disseminated lupus erythematosus, polyarteritis nodosa, the Hutchinson type of erythema elevatum diutinum, and erythema nodosum may all prove to be variations of a theme of failed allergy or anergy. They have been called "hyperergic inflammation"; but surely this term should be reserved for successful reactions of hypersensitivity which protect the shock organs, whereas hyperergy implies a partial and anergy a complete failure to react, with the result that the vascular endothelium, being "caught napping" in the unresponsive phase, is irreparably damaged by the circulating antigen, whether in the form of drug, foreign protein, or organism. Escape of the noxa and absence of the protective and diluting urticarial transudate may then lead to a secondary affection of the connective-tissue collagen. The fibrinoid reaction in the vessels and connective tissue seems to represent a makeshift stopgap measure of repair.

TIMES FOR SIGHT-TESTING

THE Working Party set up, under the chairmanship of Mr. William Penman, to discover the average time taken by ophthalmic medical practitioners to test sight, has now reported.[12] The committee finds that the average time per test is 25·2 minutes; but the total is brought up to 27·4 minutes by additions for filling up forms (1·2 min.), and writing letters to general practitioners (1·7 min.), and by an allowance to cover losses due to broken appointments (0·3 min.). From these additions, totalling 3·2 minutes, 1 minute is deducted to remedy overstatement through the concluding time of a sitting having sometimes been given as a multiple of 5 minutes. There is no evidence of widespread overwork. The three men who did most testing during the sample week made 90, 78, and 62 tests respectively, the corresponding number of sittings being 93, 81, and 79. Whole-time ophthalmologists, it seems, take on average about 5 minutes less to make a test than do their part-time colleagues. In about one-third of the completed cases letters are written to general practitioners. Conditions other than refractive errors are found in about 40% of the tests made by whole-time ophthalmologists, and in about 34% of the tests made by part-time ophthalmologists.

WE regret to announce the death on Feb. 27 of Prof. JOHN RYLE at the age of 60. He retired at the end of last year from the Nuffield chair of social medicine in the University of Oxford.

EINSTEIN'S THEORY OF RELATIVITY

R. L. WATERFIELD
M.B. Lond., M.R.C.P.
HÆMATOLOGIST TO GUY'S HOSPITAL

At the close of last century the classical experiment of Michelson and Morley showed that the velocity of light, which was *supposed to be propagated as a wave* through the æther, was the same relative to all observers irrespective of their own velocity relative to the æther. This result, which seemed to conflict with common sense, was explained by Fitzgerald and by Lorentz on the purely ad hoc assumption that the clocks and measuring rods which the observer used and which moved with him underwent changes, the clocks running more slowly and the rods contracting in the direction of their motion, to an extent depending on the ratio of their velocity through the æther to the velocity of light. This slowing and contraction, the amount of which could be calculated from the four equations of the "Lorentz transformation," precisely compensated for the motion of the measuring instruments through the æther, so that the velocity of light relative to them always came out at 186,000 miles per second.

This experiment and the explanation given implied that motion of the observer relative to the æther was for ever undetectable. Thus, while the theory of Fitzgerald and Lorentz demanded the existence of an æther, it demanded properties for it which made it impossible to demonstrate its existence by experiment—a most unsatisfactory state of affairs. But there were further difficulties. Newtonian theory required an all-pervading æther in which the force of gravity could be propagated across otherwise empty space, and electromagnetic theory required a similar medium in which light waves could be transmitted. And yet, after that, neither classical mechanics nor Maxwell's electromagnetic equations took any further interest in the æther; it might just as well not have been there.

It is an essential feature of the laws of classical mechanics that they are equally valid for all observers and *their coordinate-systems*, irrespective of their rate of motion, provided only that this motion is uniform and in a straight line. The question then arose whether this statement could not be extended to embrace *all* natural laws, not only those of mechanics. Before the Michelson-Morley experiment such a possibility could scarcely have been entertained; for how could one have *rationally* supposed that the propagation of light in vacuo with a constant velocity, itself a general law of nature, could be the same for all coördinate-systems? But now that experiment had shown that this was a fact, the above statement, which is known as the *special principle of relativity*, became much more plausible.

THE SPECIAL THEORY

At this point Einstein entered the arena and, after exposing some fundamental assumptions as fallacious, built anew *the foundations* of physics in his *special theory of relativity* (1902–05).

Einstein showed that the idea of the absolute simultaneity of two distant events was erroneous. The only way to define simultaneity is to say that if an observer is at a point equidistant *from the two events and receives* simultaneously electromagnetic (light or radio) signals of those two events, then those two events are *for him* simultaneous.

Looked at from the point of view of the æther theory, and remembering that the observer *cannot determine his* motion through the æther, this definition must imply: (1) that a second observer timing the same two events in an identical manner, but being in uniform motion relative to the first observer, will in general find that the events are *not* simultaneous; and (2) that the opinions of the two observers are equally valid, so that the *simultaneity of distant events must* be a purely relative matter depending on the motion of the observer.

But why introduce an æther and then neutralise it with such compensating effects as will make the velocity of light *appear* to be the same for all observers? *Einstein saw that the only rational thing to do* was to cut out the compensated æther and admit what after all is the only experimental datum, that the velocity of light *is* the same for all observers moving without acceleration. The relativity of simultaneity leads *directly to the relativity of all time and distance measurements*—two observers moving at different speeds past a given rod and clock will get different results for their length and rate. Moreover, the four equations which enable us to convert the time and space measurements of one observer into those of another observer moving relative to him are identical with those of the Lorentz *transformation*.

The special theory of relativity states that if the Lorentz transformation is used in converting the space and time measurements of one observer into those of another, all general laws of nature will hold with equal validity for all observers provided their motion is unaccelerated. From this Einstein made the further *deduction of the relativity* of mass. *An observer at* rest in relation to a body measures what is called its "proper mass"; but as the relative velocity between the observer and the body increases and approaches the velocity of light the measured mass increases and approaches an infinite value. That is why a *material* body can never achieve the velocity of light. *It also* follows that mass and energy are interchangeable, two aspects of the same thing; and that the two classical conservation laws must be replaced by a single law of the conservation of mass plus energy.

FOUR-DIMENSIONAL SPACE

At this stage Einstein perceived that the theory of relativity was peculiarly well suited for consideration in terms of the four-dimensional geometry of Minkowski (1908). *In the space of ordinary experience*, with its three dimensions of forwards-backwards, side-to-side, and up-and-down, it had often been convenient to look on time as the fourth dimension. But whereas by a simple rotation in your study you could convert your side-to-side into your forwards-backwards, or by going from pole to equator convert your up-and-down into one of your other two space dimensions, no such effect could be produced on the time dimension: it was quite independent of the other three. But in Minkowski's space-time all four dimensions were on an equal footing, and equally interchangeable with one another.

We have seen that in relativity theory two observers in relative motion obtain different time and space measurements. In terms of four-dimensional geometry, they divide up their space and time dimensions differently. In fact, it was shown that the use of the Lorentz transformation *in changing over from the coördinate-system* of one observer to that of the other corresponded precisely to a rotation of the coördinate-system in the four-dimensional continuum, analogous to the above-mentioned rotation in one's study.

When *you are being* driven in your car with the blinds down you have no means of deciding whether you are moving uniformly or whether you are standing *still*. But directly the accelerator-pedal is depressed, the brakes put on, or a sharp corner taken, the behaviour of *moveable objects inside* the car is profoundly modified and you are immediately aware of a change. Thus it seems that while uniform motion is relative, accelerated motion is absolute; that while uniform motion denies absolute space, accelerated motion requires it. This in itself was scarcely credible; but, apart from that, all reason seemed to demand that the relativity theory, which was so convincingly justified in the realm of uniform motion, should be extendable to embrace accelerated motion also.

Einstein perceived that accelerated motion was not quite so absolute as at first appeared. Imagine a man shut up in a chest which is far removed from gravitating matter and is being propelled upwards with an acceleration of 32 feet per second per second. It will be impossible for him to decide whether that is in fact what is happening, or whether the chest is at rest on the ground in the earth's gravitational field. On the other hand, our man would equally be unable to distinguish a situation in which his chest was in uniform motion far away from matter from one in which it was falling freely to its destruction in the earth's gravitational field. In each of the first two cases objects dropped from his hand would fall to the floor with an acceleration of 32 feet per second per second; while in each of the second two cases such objects would remain suspended in the air, moving uniformly in straight lines with whatever velocity the man happened to impart to them. But a gravitational field can be created or neutralised by rotation as well as by a linear acceleration. Thus if the chest had been lashed in empty space to a rapidly rotating disc—lashed on its side with its roof directed inwards—the occupant would have experienced a similar gravitational field; while conversely on a rapidly rotating planet the gravitational field at its equator may be partially or wholly neutralised by the oppositely directed centrifugal field.

Einstein quickly realised that the fact that gravitational fields, real and artificial (the latter produced by an acceleration or rotation of the coordinate-system), gave rise to identical mechanical effects might be of fundamental significance, and if so would point the way for the hoped-for extension of his theory. Was it possible that in the extended theory the gravitational field would emerge as a mere relation between the objects observed and the changing coördinate-system of an accelerated observer, just as in the special theory lengths and durations emerged as relations between the objects observed and the coördinate system of an observer in uniform motion?

Now, a curious property of the gravitational field, which distinguishes it from electric and magnetic fields, is that it produces the same acceleration in all bodies irrespective of their mass. If we drop a 2 lb. and a 1 lb. weight together in a vacuum they reach the ground at the same time. Yet, to give them the same acceleration, twice the force is required in the case of the 2 lb. as in the case of the 1 lb. weight. To explain this Newton had to assume that the gravitational force acting on the 2 lb. weight was also twice as great as that acting on the 1 lb. weight.

This remarkable coincidence means that the inertial and gravitational masses are always equal. If they were not equal a real and an artificial gravitational field would not be identical, and the experiments in the chest would give different results in the two cases. But if the special theory was to be extended in the way suggested above, the effects of a real gravitational field being produced in fundamentally the same way as those of an artificial field, then the gravitational mass must be the same as the inertial mass, and the equality of the two would no longer have to be regarded as an independent law of nature. Einstein saw that this argument weighed heavily in favour of the suggested extension.

THE PRINCIPLE OF EQUIVALENCE

Guided by these ideas, Einstein in 1911 put forward the principle of equivalence, which states that real and artificial gravitational fields are equivalent not only for the laws of mechanics but for all general laws of nature; for if this was not true the extension of relativity along the lines suggested would not be possible.

The importance of this principle was that it enabled one to derive the properties of a real gravitational field by simply calculating the effects of an artificial field. We know that a rifle bullet fired in empty space will travel uniformly in a straight line in relation to an unaccelerated coördinate-system. Simple calculation shows that in relation to an accelerated coördinate-system this same bullet track must in general be curvilinear. But in relation to this second coördinate-system there is a gravitational field (artificial); therefore in a real gravitational field the bullet must move curvilinearly.

But the principle takes us a step further: it enables us to argue from a bullet to a light ray and predict that in a gravitational field light also travels in a curve.

An observer is seated eccentrically on a rotating disc in empty space with a measuring rod and two clocks, one of which is fixed near the edge of the disc and the other at its centre. According to the special theory the clock near the edge, owing to its motion, must be going more slowly than the clock at the centre. Moreover, if the observer uses his rod to measure the circumference and radius of the disc he will obtain for their ratio a figure somewhat greater than π; for when he is measuring the circumference the rod will contract whereas it will not do so when he is measuring the radius.

A second observer situated outside the disc and not moving with it will ascribe these anomalies to the rotation of the disc. But the first observer can equally well contend that his disc is not rotating, but that he and his instruments are in a gravitational field which is itself the cause of the discrepancies.

Thus Einstein concluded that in a gravitational field there are no such things as rigid measuring rods and regularly running clocks, and moreover that the geometry of the region must be non-Euclidean. It was not, of course, supposed that the properties of a real gravitational field would be identical with those of an artificial field, but they would have to include those of an artificial field as a special case. And it was hoped that the properties of a real gravitational field could be inferred from those of the special case.

CURVED SPACE

The final step in the development of the generalised theory necessitated a return to the four-dimensional space-time of Minkowski with the realisation that its geometry was non-Euclidean. By simple measurement we can easily see that the well-known propositions of Euclid are not valid for a *curved* surface; the geometry of such a surface is therefore said to be non-Euclidean. For us three-dimensional beings who are not mathematicians it is easier to understand remarks about the curvature of such a surface into the third dimension than statements about its departure from Euclidean geometry. But two-dimensional beings living on the surface would be quite incapable of visualising its curvature into a third dimension and yet could readily demonstrate its non-Euclidean properties by direct measurement.

The method of investigating the geometry of such a surface was invented by Gauss. A quite arbitrary coördinate-system is constructed over the surface and measurements are made on the surface in relation to this system. From these measurements certain coefficients are obtained, which, when analysed, reveal not only the nature of the coördinate-system but also the nature of the geometry of the region. But why introduce an unnecessary complication by constructing an arbitrary coordinate-system? Why not in the first instance draw up some perfectly regular mesh-system? The reason is that the type of mesh-system is partly determined by the type of curvature of the surface, and in the problem at issue one cannot know that in advance.

In precisely the same way the geometry of our four-dimensional space-time can be investigated by making measurements in relation to an arbitrary four-dimensional Gaussian coordinate-system constructed in it. Any departures therein from Euclidean geometry can thus, by analogy with a two-dimensional surface, be looked on as "curvatures" of the four-dimensional space-time into still further dimensions.

It will be noticed that the arbitrariness of the Gaussian mesh-system corresponds with the arbitrariness of the non-rigid rods and irregular clocks which we saw had necessarily to be used in a gravitational field. The actual form of this mesh-system will depend (1) on the arbitrary way in which it is laid down, (2) on the kind of acceleration it and the observer have in three-dimensional space, and (3) on the curvature impressed on the continuum by the presence of gravitating matter.

The problem remained to find the law governing the curvature of space-time in the vicinity of matter—in fact, the law of gravitation. This law would have to be such that in the special case of an artificial field it gave rise to a distortion of the mesh-system identical with that corresponding to an acceleration (linear or rotational) of the observer and his coordinate-system; and also such as to give an approximately "flat," or Euclidean, space-time at great distances from matter. This was the law which Einstein finally discovered about 1915.

In empty regions of the four-dimensional world the track taken by an object moving freely from one point to another in space-time must be uniquely definable—otherwise the object could not decide which track to adopt and chaos would result. In ordinary space the unique track of a freely moving object between two points is the shortest distance between them, the straight line. In the four-dimensional world the corresponding uniquely definable track between two space-time events is called a geodesic. Though it is impossible to draw a straight line on a curved surface, such as that of a sphere, one can define a unique line between any two points on it, namely a *great circle*. Even if this surface had localised curvatures in it, such as hills and valleys, one could still define a unique track between any two points, though, since it must follow the curvatures of the surface, it would be of more complicated form. Similarly in the four-dimensional world one can still define geodesics uniquely even in the "curved," non-Euclidean, regions in the vicinity of heavy bodies.

According to Einstein's theory the four-dimensional track of every material body, so long as it is not impeded by actual collision with other bodies, will be a geodesic; far from matter the geodesics are straight and correspond with the state of rest or of uniform motion in a straight line in ordinary space; but in the neighbourhood of matter they follow the curvature of the surrounding space-time and give rise in ordinary space to the characteristic elliptical orbits of the planets and double stars.

It will be seen that the geodesic "law" is not an independent law, but emerges as a necessary consequence of the geometrical nature of the theory. Thus Einstein's law not only replaced Newton's law of gravitation but also his three laws of motion and the law of the equality of gravitational and inertial mass. It also did away with the necessity of assuming a mystical force of gravity which could be propagated across empty space.

Except in the case of very rapidly moving bodies or of very intense gravitational fields the new theory gave the same results as Newtonian theory. So far only three cases are known where the results of the two theories differ sufficiently to form a crucial test: an anomaly in the motion of Mercury, the fastest moving of the planets; the bending of light when a ray passes close to the sun's surface; and the slowing-up of atomic vibrations producing a shift in the spectral lines of very dense stars, where the gravitational field at the surface reaches unusual intensity. The results of the first of these tests agree precisely with the theory; those of the other two agree within the uncertainty of the observations.

THE UNIFIED FIELD THEORY

The generalised theory of relativity, while accounting for the gravitational field, completely ignores the electric field. Yet reason seems to demand a still more generalised theory which will embrace both the gravitational and the electric fields: a so-called "unified field theory." The first solution of this problem, a welding together of electricity and gravitation into a single geometry, was achieved by Weyl in 1918; and in the last thirty years other solutions have been produced by Eddington, by Einstein himself, and by others. But though some authorities have considered them convincing, it has not been possible to put any of them to a crucial experimental test. Einstein has now produced another solution which he regards as fully satisfactory and which has lately been acclaimed in the press as "Einstein's new theory": but again he cannot yet point to any means of testing it.

DOCTORS IN PARLIAMENT

NINE medical men and one medical woman have been elected to the new House of Commons. Dr. Charles Hill and Dr. R. F. B. Bennett are newcomers; all the others were members of the last Parliament.

R. F. B. BENNETT, V.R.D., B.M. Oxfd (C., Gosport and Fareham), was born in 1911 and educated at Winchester, Oxford, and St. George's Hospital. After taking the L.M.S.S.A. in 1937 he held a psychiatric registrarship at St. Ebba's Hospital, Epsom. He took his B.M. in 1942. During the war he served as a surgeon lieut.-commander in the R.N.V.R. and he was twice torpedoed. He has since held a psychiatric registrarship at the Maudsley Hospital and a registrarship in psychosomatic medicine at King's College Hospital. Well-known as a yachtsman, he was a member of the team which competed last year for the British-America Cup.

A. D. D. BROUGHTON, M.A., M.B. Camb. (Lab., Batley and Morley), who is 47 years of age, was returned as M.P. for this constituency in a by-election in 1949. A native of Batley, where his family have practised medicine for over 70 years, he was educated at the grammar school there and at Rossall School. He studied medicine at the University of Cambridge and the London Hospital where he qualified in 1929. He held the post of medical officer at Rossall School before he settled in practice at Batley in 1932. During the war he served for five years with the R.A.F.V.R. with the rank of squadron-leader.

WALTER ELLIOT, P.C., M.C., M.B., D.SC., F.R.C.P., F.R.S. (C., Glasgow, Kelvingrove), who sat for the Scottish Universities in the last Parliament, has now been once more returned by the Glasgow constituency which he represented from 1924 to 1945. He was born in 1888; he graduated in science at Glasgow University in 1910 and in medicine in 1913; and he holds honorary degrees from five universities. During the first world war he served with the R.A.M.C., and he first entered Parliament in 1918. He has held office as Minister of Agriculture and Fisheries (1932–36), Secretary of State for Scotland (1936–38), and Minister of Health (1938-40).

SOMERVILLE HASTINGS, M.S. Lond., F.R.C.S. (Lab., Barking), is consulting surgeon to the ear and throat department of Middlesex Hospital, London, president of the Socialist Medical Association, and alderman and former chairman of the London County Council. He is also chairman of the board of governors of the Hammersmith, West London, and St. Mark's Hospitals. He was born in 1878.

CHARLES HILL, M.A., M.D. Camb. (C. and L., Luton), who is 46, is secretary of the British Medical Association. He was educated at St. Olave's School and Trinity College, Cambridge, where he obtained first-class honours in the natural sciences tripos in 1925. In 1927 he qualified from the London Hospital. He was deputy M.O.H. for Oxford before he joined the staff of the B.M.A. He is president of the World Medical Association. He is already known far beyond the medical profession by the talks on health which he has given as the Radio Doctor; and his mastery of this modern technique was shown to advantage in his election address.

Dr. A. D. D. BROUGHTON

Dr. CHARLES HILL

Mr. WALTER ELLIOT

Dr. BARNET STROSS

Dr. EDITH SUMMERSKILL

Dr. H. B. MORGAN

Dr. S. W. JEGER

Mr. SOMERVILLE HASTINGS

Dr. R. F. B. BENNETT

Colonel STODDART-SCOTT

S. W. JEGER, M.R.C.S. (Lab., Holborn and St. Pancras South), who is 51, was educated at University College, Cardiff, and the London Hospital. After qualifying in 1923 he settled in general practice in East London and the West End. A former mayor of Shoreditch, he was one of the founders of the Socialist Medical Association.

H. B. MORGAN, M.D. Glasg. (Lab., Warrington), represented Rochdale in the last Parliament. He is medical adviser to the Trades Union Congress and several trade unions. Born in 1885, he was educated in the West Indies and Glasgow University, where he qualified in 1909.

Colonel **MALCOLM STODDART-SCOTT**, O.B.E., M.D. Leeds (C., Ripon), sat for Pudsey and Otley in the last Parliament. He is 49 and qualified in 1926. During the late war he was A.D.M.S. of the 48th division. A member of the executive committee of the British Social Hygiene Council and of the West Riding Fitness Council, he is also a vice-chairman of the British Rheumatic Association.

BARNET STROSS, M.B., M.SC. Leeds (Lab., Stoke-on-Trent, Central) who was elected for Hanley in 1945, is medical adviser to the North Staffordshire Miners' Federation and the National Society of Pottery Workers. He was born in 1899 and he qualified in 1925. The following year he settled in practice in Stoke-on-Trent.

EDITH SUMMERSKILL, P.C., M.R.C.S. (Lab., Fulham West), has been parliamentary secretary to the Ministry of Food since 1945. She was appointed a privy councillor in 1949. Born in 1901, she qualified from Charing Cross Hospital in 1924. She is the wife of Dr. E. J. Samuel and has two children.

Dr. Bennett's photograph is by the *Evening News & Hampshire Telegraph*, Dr. Hill's by Elliot & Fry, Colonel Stoddart-Scott's by Navana. The remainder are reproduced by courtesy of Press Portrait Bureau.

CONFERENCE IN WELLINGTON

FROM OUR NEW ZEALAND CORRESPONDENT

The biennial conference of the New Zealand branch of the British Medical Association was held in fine weather in Wellington from Feb. 14 to 17, under the presidency of Mr. E. H. M. Luke. There was an enjoyable programme of social and sporting events, including a dinner and ball. Each day, combined and sectional meetings were held in Victoria University College. The chief subjects were congenital heart-disease, amœbiasis, cancer of the breast, the fenestration operation, aviation medicine, hypertension, hiatus hernia, gastric surgery, carcinoma of cervix, the anticoagulants, and medicolegal problems.

Special addresses were given by Mr. Arthur Porritt, of London, in memory of New Zealand medical men lost in war, and by Dr. R. S. Aitken, vice-chancellor of Otago University, on standards in medicine. This was a valuable and critical survey, with an eye to the future, of possible methods of raising and maintaining standards in practice. Mr. Porritt also participated in the discussion on gastric surgery. The president's address was on the Doctor and the Patient in 1950 and dealt with contemporary modes in practice. Mr. J. T. Watts, the minister of health, addressed the conference on the same occasion. Both the minister and high officers of the B.M.A. expressed readiness to coöperate towards the common good during necessary revision of social-security legislation.

AUCKLAND UNIVERSITY COLLEGE

Mr. K. J. Maidment, formerly of Merton College, Oxford, has arrived and taken up duty as first principal of Auckland University College. His colleagues in the other three centres have already assumed office, and joined the senate. Mr. Maidment begins at a time of lively discussion of university policy in general and in New Zealand in particular. In only twenty-five years the college has badly outgrown its site and buildings, and eyes are cast towards Tamaki, five miles from the centre of the city, where an empty site of 120 acres has been acquired; there are still no definite plans for building.

Points of View

WAR

ITS ORIGIN IN THE MINDS OF MEN

RANYARD WEST

M.D. Lond., D.Phil. Oxfd; M.R.C.P.

I. Minds, Ideas, and War

Do wars arise in the minds of men? The preamble of the UNESCO charter says they do.[1] Why did its authors think so? The draftsmen of that document may have thought of evil minds corrupting good minds—with a side glance at the Nazis. Or they may have thought of the acquisitive and aggressive passions of normal men flaming up spontaneously or when played upon by the winds of chance. They may have been impressed by the curious fact that, when everything is laid out after a war, nobody seems to have wanted what everybody actively took part in: and thus they may have been drawn to the deduction that Grotius made early in the 17th century, that war is "a madness driving men to all kinds of crime." They clearly did not accept the doctrine to which professional students of politics most often adhered before the recent war—that wars arise from inevitable economic necessities.

It is not a simple task to examine the accuracy of the UNESCO preamble in this matter of the mental origins of war. One difficulty arises from the imprecision of the term "mind." To many people the mind is something quite distinct from the body, a spiritual entity: to others it is "just mechanism." In using this term I shall mean the higher functions of the brain in respect of thought and feeling—our intellectual processes and our emotions, conscious and unconscious.

For all higher functions, however, psyche and soma are wrapped up together, in that motor responses of the mind are influenced by somatic health—neural and humoral—and in their turn influence the health of the soma wherever they reach it. It would seem then that if wars can arise in the minds of men they may also arise in their bodies. Moreover, since the interrelation between the external and the internal environment of a person is continuous, whether in respect of mental function or somatic function, the environment modifies the responses of that person in endless ways. Hence, philosophically speaking, all that it seems possible to say about our inquiry is that wars, like every other human activity, may find predisposing and exciting causes in the constant interaction of human persons with their human and non-human environment.

But the challenge that "wars arise in the minds of men" is clearly intended to mean something more precise than that men have something to do with the start of wars. And since UNESCO was intended to diminish the risks of war by the ardent use of the human brain, let us see whether we can help UNESCO with its task a little better than by dousing its initial tenets with destructive criticism. Let us therefore take another tack.

IDEOLOGIES

While the interrelationships of mind, body, and soul have been and will continue to be the subject of much varied philosophy, ardour, faith, and scepticism, we know that the politics of men remain passionately and continuously in conflict, though the scene of conflict frequently shifts. Is there any demonstrable connection between the two spheres—between our diverging fundamental philosophies and our political quarrels? In other words, how far are diverging philosophies of life, systems of ideas, or ideologies a fundamental cause of human strife?

---

[1] See also the article on International Tensions by Otto Klineberg, *Lancet*, 1949, ii, 851.

Again it is not easy to answer. Ostensibly quarrels are often due to ideological conflict. But is the ideological difference the primary one? Are there not often long-established cultural, vocational, climatic, and racial traits behind the different ways of men's lives and thoughts, including their political thoughts? For example, hundreds of years of rich pasture seem to have left their mark on southern British character, contrasting with that of the hard-striving, potato-shortage economy of the north. In Ireland, again, more Celts and fewer Norsemen have combined with a mild damp air, and heaven knows how many other indigenous differences, to produce a very different response to potato shortages from the determined and anxious foresight of the Scots. When to ancient race and perennial soil and climate we add social history—pastoral, agricultural, urban, industrial—we can see how they all contribute their quota to ideology before we get to the experience which each individual extracts from the times he lives in. The psychoanalyst then demands that we look deeper than the obvious, as well as further back than the obvious, for the raw material of character and personality, be it individual or racial.

Any system of ideas held by individuals or groups must thus depend on very many factors, past and present. But in the outcome political ideas can be seen clustering in certain places, particularly among organised and coherent social groups and notably today among social classes and sovereign nations. Here they cluster and cause strife. The French proletariat revolted ideologically in 1789, the Russian in 1917, that of nearly all Europe abortively in 1848. On the other side of the Atlantic a few centuries of different general climate, and an initial difference of structure of society, developed in the North and South a different general psyche which seemed to contribute its quota to the bitter tragedy of the American Civil War.

Such historical conflicts seem parochial today as we stand on our suddenly widened 20th-century stage and look over our shoulders at the rapid ascendancy and eclipse of *Deutschtum*—with its peculiar economic pressures, its peculiar history, and its racial traits of body, mind, and soul—and forwards to possible conflict between the once "united" victors in that struggle. Today we see on the one hand "Russian Communism" with its peculiar psychosomatic-economic-racial history, so near in much of its experience the history of half the peoples of the world, and on the other the organised, and powerfully successful "individualists" of the North Atlantic shores. How, one may well ask, can anyone see such a threatened world and not regard the politics of mankind as in the largest sense environmental in origin, and its wars as due to an inevitable mixture of economic and philosophical differences?

If that be so, why not be content to speak of "ideological conflict" and turn this article over to the economists and political scientists? The answer I believe to be that such an analysis is wrong; nor does it even touch the proper contribution for a medical philosopher to make to sociology today.

Let us look again at our ideologies, noting how political and economic theories alike appear to be at the mercy of something else. Ten years ago the English Socialists still held that the Marxian analysis was broadly right, though national ownership, gained through the ballot-box, would do more for the welfare of the proletariat than revolutionary Communism. But today the party whose banners used to proclaim "Hands off Russia" leads the anti-Communist crusade. Political history is full of such changes, suggesting that ideology—a system of consistent political ideas—is seldom an overriding element in the political behaviours of peoples. Ideologies consist of ideas, and these are shouldered out by new ideas, the product of new circumstances. It is not ideology that we see surviving, but nationalism. And whether we look at victorious nation or defeated nation, at the first world war or the second world war, it is nationalism that fights and it is nationalism that remains.

One may hazard the guess that since nations became the universal effective units of power three or four centuries ago every war that has been fought has been a nationalist war, excepting only where the power of the nation became divided in the faction of civil war. It is, in fact, not ideology but the *power-group unit* that primarily excites the effective loyalty of war-making mankind.

II. Nationalism, Loyalty, and War

The nation State requires that wars should be national. However great their urge to war, religious groups, political groups, the devotees of ideal and ideology, the protagonists of the right to atheism, free speech, primitive Socialism, or antivivisection, all have to grin and bear with each other so that only the nation shall retain the right to strike its enemies.

It was not always so. In the 17th century the Huguenots were able to have their wars both within and across the national boundaries of France. At the same time French Catholics did not know whether to be Frenchmen first or Catholics first; and that sort of problem continued to a comparatively late date. Even quite recently some of us expected good Germans to repudiate the national government of Hitler while it was both in power and at war! Americans could fight each other about slavery, cotton, and other matters until Abraham Lincoln gave them a national government organised as such. German princes enjoyed the same right before the creation of the German Empire. What makes the difference is probably simply the centralisation of power. Overriding power to levy taxes, the sole control of the armed forces, the exclusive claim to represent its people as a whole at home and abroad—these were the discoveries that made the difference because they *established one Power transcending all others within the State.* From the time that autocrats, parliaments, and bureaucrats discovered and seized these essentials of control, theories might come and theories might go, but the de-facto national government alone declared and conducted the wars that arose in the minds of men.

But the government of the nation only took over this function of controlling and expressing group power from its various predecessors, feudal barons, Continental princelings, clans, city States, the leaders of tribes and herds. As for us subjects of government, it looks as if the powerful organisation of our group interest (or seeming interest), aggressive and defensive, still fixes the loyalty of our minds in a primitive, unquestioning, biological sort of way. A demonstration of overriding power in our name, in the presence of external threat or imagined danger, works the magic of obedience in our minds. Obedience and something more. The power we accept, with varying degrees of enthusiasm, as ours. The enemy we see, with varying degrees of distaste or fury, as evil. Our leaders lead us in judging, with varying degrees of prejudice, our own cause. Their means of publicity portray selected facts with varying allegiance to truth. And, though we can never see it so at the time, every other national government and people does exactly the same thing with just the same result. It is not a case of power corrupting; but of power—the only remaining repository, for good or ill, of the group force of mankind—hypnotising us in an entirely primitive and old-fashioned way. In national loyalty and enthusiasm do we not witness a long-established reflex involving the mind? The thought process which accompanies the reflex may be broadly expressed as: "We are a power-group, successfully surviving because we have previously stood together against competing enemy groups. There must be enemies: there always have been. Where are they? What are they already up to? Ah! . . ."

LOYALTY

Next it is worth remembering—indeed it is essential to remember—that as gregarious human animals we can only be efficient if we are loyal *to the death*. Our high valuation of loyalty in war-time is probably far more instinctive than intellectual, though intellectual reasons for being loyal to a good cause can always be found. It is important to note what a strong basic emotional response this requires of the self-centred, pleasure-loving, and life-loving normal human being. That he should be able, at comparatively short notice, to find his group's cause worth dying for, whatever that cause may be, is not the least remarkable feature of the body-mind of *Homo sapiens*. It has become a sublime tragedy of the race.

Loyalty may be more effective if it is entirely "voluntary." In general it is probably weakened by compulsion, though psychology can show mental mechanisms that provide for the exception. In the case of modern man it may have been weakened by universal State conscription. But conscription has by no means killed voluntary individual self-sacrifice to the welfare of the human herd by its members. Faced with the alleged motives and the actual moves of the enemy—and, whether in private fisticuffs or international tensions, every defensive movement of the enemy looks offensive from the other side of the ring—faced with the war that passes from the inconceivable and unlikely to imminence and the actuality of our fellows' dying for the cause, conscience pricks the man who cannot show at least a fairly active acquiescence in his own extinction then.

> Have *I* the right to whisper "I remember"?
> I was not with them when they marched away.

The theory of Socialism and the theory of Communism should each of them have tended to counter our present national biological trend to war. But the political parties that adopted these doctrines were able to counter it only while they remained in opposition and themselves separate from and devoid of national power. With the advent of Communism to power in a single State, the idea of the workers of the world uniting became converted (slowly, and it may yet prove incompletely) into the idea of the workers in enemy countries undermining the national forces arrayed against the Russian State. And, with the door opened by modern war and the State Socialism it seemed to necessitate, Socialist Britain has surprised many observers, and disappointed some inveterate pacifists, in its demonstration that, with the best will in the world in certain places, Socialism in power becomes National Socialism.

The fault here, if fault it be, does not seem to lie in the Socialism or the Communism, each of which is a doctrine of a way of living and of organising society alternative to liberal democracy in the present, monarchic autocracy or feudalism in the past. National Socialism is not Hitlerism, though the horrid elements of tyranny and persecution easily creep into any power system which works under great stress. National Socialism is Socialism wholly limited by national blinkers, and seeking first of all the prime welfare, and in the end (as I think must always happen) the desperate survival, of its own nation State in a world of competing nation States which are the logical and emotional heirs to the tribe and the clan.

We can hardly find that wars arise in the minds of men because there are ambitious tyrants about. We are dealing with the modern world, and no modern State would long tolerate a tyrant in quiet times. Our times are unquiet, not because tyrant faces tyrant—or even because tyrant faces freeman—but because nation faces nation in competition, fear, dislike, and conflict. The quality in the mind is a basic human quality. Wars arise because the minds of ordinary persons of every nationality react in certain definite and constant ways to certain recurring circumstances in the tensions between power-groups.

We must consider further the universal circumstances which determine war, and how those circumstances can be controlled.

(To be concluded)

Disabilities

46. THROMBOANGIITIS OBLITERANS

I JOINED the Army in the early days of the late war, at which time I was organically sound, though, like many general practitioners, in a constant state of jadedness owing to some 20 years of overwork, hurried meals, late nights, and heavy smoking (I usually smoke some 20–30 cigarettes a day).

Whatever the drawbacks of Army service, it at least enables one—unless one's rank is exalted—to cast the familiar cares aside, and so within ten days I found myself, though no chicken, being then aged 42, in very good health indeed. As a subaltern in a rather strenuous field ambulance, where the C.O. insisted on a training as rigorous as that of a fighting unit, I found I could hold my own with fit young men in their early twenties, march 30 miles well laden, and play strenuous games without being more tired than anyone else.

This agreeable state continued for about two years, until 1942. By that time I had passed the subaltern stage and was commanding a convalescent depot, the main function of which is to toughen men up again to a high standard of fitness. Here my duties were largely sedentary, but with bursts of what was to me violent exercise, when I personally tested batches of men who were fit to return to their units. These tests included the usual strenuous games, cross-country runs, and a very quick forced march of 12 miles.

My first symptom appeared on one of these marches, when soon after setting off I felt as though my left gaiter was too tight. I fell out and loosened it, doubled up and rejoined the column, and completed the march without further trouble, except that my gaiter still felt slightly uncomfortable.

In the next twelve months my leg gave me little inconvenience, but in 1943 I was posted to a unit standing by for the coming campaign in Europe. This year of waiting was passed mainly in physical exertion of one sort or another, cross-country runs and marches predominating, with a weekly climb at top speed over two or three of the summits of the Pentland Hills near Edinburgh. These marches were often done in cold weather, through some inches of snow. I thoroughly enjoyed these exertions, and it was mainly of my own choice that I participated in them. By now, however, I was having the "tight gaiter" feeling on every march, and rather more severely. It would pass off if I ignored it, and by developing a technique of walking which spared my calf muscles I was able to keep up with the others.

Curiously enough, even at this stage, I remained blind to the fact that I was having intermittent claudication and I attributed my pain to muscular strain or fibrositis of some kind. It was not until nine months later, when I was in Normandy and no longer taking strenuous physical exercise, that, in addition to the now easily induced pain in the left calf, I began to have a very troublesome coldness in both feet, mainly in bed at night, which resisted all attempts to warm them up by rubbing, &c.

Gradually I diagnosed my own condition. By now it was clear enough, for I had no pulsation in either the dorsalis pedis or posterior tibial artery of my left foot. My toenails were assuming an exaggerated curve from side to side and were slightly ingrowing and more brittle than before. When I got into a hot bath, especially after previous exertion, my left foot would become peculiarly numb, and pale, with purplish mottled lines and patches. I had my blood-pressure taken at this stage and it was normal at 125/90 mm. Hg. An X-ray film of the arteries of my legs showed no calcification.

I could still get about remarkably well, and I returned to general practice in August, 1945. Here I was hardly aware, except for cold feet at night, that anything was amiss, until one day my car broke down 200 yards from home. I set off walking to my house rather quickly and in some anxiety, for I had a big round to do and little time to spare. Within 50 yards I was pulled up with the most severe pain in the leg I had yet experienced and was only able to reach my house with difficulty and grotesque limping. I afterwards noticed that exertion plus mental unrest always produced the pain more quickly than exertion alone.

I now developed what was to me the most distressing feature of the complaint. The full significance of the disease became suddenly apparent to me and in a very short time this led to a feeling of the utmost depression. The future seemed gloomy, forbidding, and hopeless. Out-of-door pleasures—sport, gardening, and the like—and even indoor ones such as dancing were no longer for me. Work, though still well within my capabilities, became a grievous burden, unleavened by even the previous short episodes of relaxation and pleasure. I became morose and short-tempered towards those who least deserved this treatment. Even thoughts of eventual suicide began to lurk not very far back in my mind. Finally I realised that I could not go on like this much longer and I put myself in the hands of a very competent surgeon who was also a good friend of mine; though I had no great hopes of deriving much benefit from treatment.

A bilateral lumbar ganglionectomy was performed, under spinal anæsthesia, in March, 1946—i.e., about five years after the appearance of the first noticeable symptom. The improvement in the warmth in my feet was striking as soon as the anæsthetic had worn off, but the first fortnight of convalescence from the operation was very unpleasant. The operation was done by the transperitoneal route from the front of the abdomen, and an over-abundance of veins round the ganglia made it difficult and entailed more handling of the bowels than usual. This presumably led to a mild paralytic ileus.

After the first three weeks I was conscious of a vast improvement in my mental outlook, and within four weeks I could walk several hundred yards, though rather slowly because I was cowardly of testing myself too severely in case I found that the operation had failed. This fear was based on a paper I had read during my stay in hospital; it summarised the results of ganglionectomy in Buerger's disease and made very depressing reading. However, such was the improvement in my spirits that I felt that I was to be an exception to the rule, and further tests of my capabilities confirmed my optimism.

In two months I was trout-fishing again. I spent a good part of one afternoon wading, without waders, in a very cold upland stream, and, though the water felt cold, my feet got warm again as soon as I regained the bank—so much so that I looked at my bootlace holes half expecting to see steam issuing forth. In another two months I was playing 18 holes of golf without trouble, though I found it a great help then and now to take two sticks with me to take the weight off my toes when walking. I can manage without if I am content with 2 miles an hour, but with walking-sticks I can go almost any reasonable distance at full walking pace.

This state of affairs has continued until the present day and I trust that it may continue—though perhaps I am hoping for too much.

As the result of the mental upset through which I passed, before and immediately after the operation, I decided that I must get a little more leisure and pleasure out of life than can be got in a busy practice. God's countryside and the quiet places, and the leisure to enjoy them, had never seemed more desirable than in my period of black depression. So I have edged out of the struggle and come to a remote but beautiful island in the Hebrides.

Here, with only 250 patients to tend, I can do the slight amount of work easily and without fret or hurry. Taking my own time I can reach my most distant crofter, or the most distant trout lock over rough moor, without trouble. Once, without sticks and carrying a 12-bore gun, I walked 6 miles over sand dunes after wild geese. I gather my own peats, care for a biggish garden, catch my own fish and lobsters, and do the rougher household chores—so I have no time for boredom. At the end of my day I feel at peace with the world and most grateful to my good friend the surgeon.

* * *

To summarise, these are the outstanding points of Buerger's disease as it has come to my notice:

(1) The very gradual onset of symptoms, increasing irregularly with intervals of less severity. The appearance of cold feet is of much import, because after that the condition can no longer be laughed off.

(2) The significance of really strenuous exertion, especially of a semicompetitive type, as a causative factor in those no longer young. This was strikingly illustrated in the unit in which I latterly served. Out of a permanent staff of 90 men, many of whom, though fit, were above the usual Army age and yet had at least attempted the exertions I have described, no fewer than 3 developed well-established Buerger's disease. An incidence of $3^1/_3\%$ surely cannot be ascribed to chance.

(3) The tendency to severe depression.

(4) The good results of a thorough bilateral lumbar ganglionectomy. The results might well be better if the operation were done before irreversible changes had taken place. (I still have no dorsalis pedis pulse, and in fact cannot feel my left popliteal artery.)

(5) The value of escape to peaceful surroundings.

(6) The suspected influence of heavy smoking. Some people smoke 60–70 cigarettes a day with no apparent effect, whereas others lose their appetite and get dyspepsia, headaches, or tremors of the hands on 15–25 daily. I belong to the second, more vulnerable, class, but whether this had anything to do with my trouble is hard to prove.

(7) The possible contributory effect of faulty posture. I always sit with my knees crossed at a sharp angle; is it unreasonable to suppose that the popliteal artery may be damaged by years of this attitude?

Medicine and the Law

Professional Privilege

PRIVILEGE in connection with medical records under the National Health Service Act has lately been discussed by Nokes.[1] Ever since the end of the 18th century the courts have declined to recognise any privilege for communications by a patient to a medical practitioner in private practice. Many States treat medical confidence as privileged, but England remains an exception.

In the National Health Service the confidential relationship of doctor and patient has been further breached; for general practitioners are required to forward records of patients to executive councils; and Nokes observes that "it can hardly be anticipated that documents will not pass from one office to another." However, the National Health Service Act (sect. 13(2)) refers expressly to the right of the Crown "to withhold or procure the withholding from production of any document on the ground that its disclosure would be contrary to the public interest," and this State privilege has been claimed from time to time by various Departments, including the War Office.[2] Nokes concludes that—

> "the nationalisation of medical service produces the anomalous situations that disclosure in Court is dependent upon the will of the Minister; that even if the Ministry does claim privilege the previous liability for disclosure in Court is merely exchanged for disclosure to officials; *and that if the Ministry does not claim privilege there may be disclosure both to the officials and the Court.* . . . Thus it would seem that the new service may have a very limited effect upon the normal obligation of disclosure in Court by a medical adviser. But if Crown privilege is widely exercised, it may obstruct litigation in almost any sphere."

Blood Tests in Paternity Dispute

In a recent action concerning the legitimacy of two children, Mr. Commissioner Grazebrook, K.C., found himself unable to accept medical evidence of blood tests as conclusive.

A husband had obtained a divorce and his former wife had remarried. She applied to the court for maintenance for two children, aged 4 and 2, born before the marriage was dissolved; he denied paternity. A doctor gave evidence that in the case of one child ordinary blood-grouping showed that the first husband could not have been its father; four other tests, it seems, were inconclusive.

The Commissioner said that only one of the two children was affected by the evidence. After the husband had separated from his ex-wife in 1944 he had occasionally visited her, in order to see the children, until he obtained a decree nisi (in July, 1948) in an undefended divorce petition. The Commissioner observed that there were opportunities for marital intercourse at the material time; there was no evidence which he could accept to establish that relations did not take place.

This was stated to be the first case to be decided since the Law Reform (Miscellaneous Provisions) Act, 1949, had come into force. It may be recalled that in 1924 the House of Lords held in Russell *v.* Russell that neither spouse could give evidence tending to show that he or she did not have marital intercourse, if such evidence would tend to bastardise a child prima facie born in wedlock. This ruling was the more surprising because there was a long-standing practice in the Divorce Court to admit a spouse to give evidence of non-access. The trial judge had held this practice to be right and the Court of Appeal had confirmed his view; but the House of Lords, by a majority of 3 to 2, held that the evidence was inadmissable. The consequent position caused great inconvenience. If the wife of someone serving in the forces overseas during the war went off with another man at home and children were born of which the husband could not possibly have been the father, cumbrous arrangements had to be made to call evidence from some other source (from the regimental depot, for example, or the commanding officer) to prove that the husband was abroad at the material times. The rule in Russell *v.* Russell had already been abolished by statute in South Africa and in several of the provinces of Canada. The 1949 Act abolished it in England. If this change of the law was not decisive, in the recent case referred to above, *it is a reminder of the reluctance* of the English courts to investigate the marital relations of husband and wife during a subsisting marriage.

Public Health

Influenza in England and Wales

A YEAR ago the number of deaths due to influenza in the 126 great towns rose from 66 in the week ended Feb. 5 to 171 in the week ended Feb. 19. This rise was the first clear sign of an increase in incidence which might reach epidemic proportions. Subsequently mild influenza became widespread, and deaths reached a peak of 379 in the week ended March 19. The outbreak, due to virus A, appeared to be part of a wave of infection spreading across the Continent.

This year, although from many areas there are reports of a high prevalence of respiratory disease, there is no sign of a continent-wide spread in Europe. In this country specimens received by the Virus Reference Laboratory from patients suffering from influenza-like *diseases have not been numerous, and influenza* virus has been recovered from less than half a dozen localities. Such evidence as there is from virus and serological examinations suggests that these local outbreaks are due to virus B. Virus A has so far this year not been recovered in England and Wales.

The figures for influenza deaths and for pneumonia cases and deaths are as follows:

Week ended	*Pneumonia* *Cases*	*Pneumonia* *Deaths*	*Influenza deaths**
Dec. 24, 1949	384	299	27
Dec. 31	496	310	28
Jan. 7, 1950	639	299	52
Jan. 14	550	300	47
Jan. 21	487	233	39
Jan. 28	198	305	47
Feb. 4	594	354	61
Feb. 11	582	378	80
Feb. 18	630	353	76

*Including deaths from influenzal pneumonia.

In the first seven weeks of the past three years the figures for the great towns have been as follows:

Year	*Pneumonia* *Cases*	*Pneumonia* *Deaths*	*Influenza deaths*
1948	3362	1935	145
1949	4217	2516	486
1950	3980	2222	402

The incidence in England and Wales of primary and *influenzal pneumonia in corresponding weeks of* 1949–50 and 1948–49 was as follows:

Week ended	*1949–50*	*1948–49*
Dec. 24	634	792
Dec. 31	842	1050
Jan. 7	1120	1184
Jan. 14	991	1184
Jan. 21	890	1050
Jan. 28	902	935
Feb. 4	1187	1016
Feb. 11	1228	1139
Feb. 18	1189	1469

Up to the week ended Feb. 18 there is nothing to suggest that the incidence will reach epidemic proportions. The United States Commission on Acute Respiratory Diseases[1] suggested that virus B might be endemic and only occasionally erupt in an explosive form. In this country, *too, virus B appears to be endemic and outbreaks due* to it strictly localised.

Population of England and Wales

The Registrar-General's latest estimate[2] of the populations of each local-government area in England and Wales shows that at June 30, 1949, the total population was 43,595,000, of whom 9,497,000 were under 15 years of age.

In England Now

A Running Commentary by Peripatetic Correspondents.

English pronunciation has undergone remarkable changes through the centuries. One striking, but not to my mind euphonious, result has been the transformation of the long "i" from the sound it represents in most European languages, and which we now render by the letters "ee," to the rather Cockney diphthong pronounced just as the word "eye." I became strikingly aware of this during war service in Italy, when contrasting the native with the current English versions of such familiar adjectives as Pontine, Capitoline, or Apennine. Similarly I realised that the pronunciation of Latin which I was taught at school must have rendered it as unlike the Mediterranean tongue as it could possibly be. Years ago, Latin was an international language for an educated European, but now we have to give our many medical words of Latin derivation unfamiliar Italianate values if we want them to be understood by visitors from the Continent. I was amused to hear an eminent visiting Italian professor baffled by the words "culture positive" until they had been changed by alteration of the vowel sounds into the "*cultura positiva*" of his own language.

Our American friends still refer to the "Philipp-EE-*n*" Islands, thus keeping nearly to the Spanish usage. Nevertheless, I rubbed my eyes the other day when, in an American article on neoplasms arising near the bifurcation of the trachea, I saw the word "coryna." I thought at first it was a mistake, but it was repeated several times. It is exactly thus, of course, that many of us habitually pronounce "carina" when referring to the sharp ridge separating the orifices of the two main bronchi. The word originally meant the keel of a ship, and it passed into English usage in former days, with its vowel sounds faithfully preserved, as the verb "to careen." This will be familiar to readers of history and boys' adventure stories as meaning to clean the fouled hull of a sailing ship. But we moderns have forgotten this and have changed the pronunciation in our vulgar way until now "coryna" can pass the proof-reader.

"Coryna" looks like a word with a Greek ancestry, and an Athenian friend tells me that there is a modern Greek word which would be so rendered in English. It signifies an article of gymnasium equipment, resembling an Indian club. I have, however, looked down my bronchoscope many times since learning this interesting fact and am bound to say, albeit with some regret, that the ridge between the bronchi resembles more the sharp keel of a ship than the rounded surface of an Indian club. I am afraid the standard spelling must stand.

* * *

When my wife demands cough medicine for our obviously healthy young son I reflect ironically that cobblers' children are traditionally ill-shod. The weight of opinion in my practice forces me to prescribe barrelfuls of expectorant mixtures daily though all the recent literature questions their rationale. It is strange that my patients should be the arbiters rather than the pundits whose words I so reverently accept. For a pharmacologically incompatible blunderbuss like mist. expect. is far more popular than the scientifically respectable linctus codeinæ. But my wife is as persistent as my most insatiable patient, and as I docilely fill in an E.C.10 I wonder whether the cobbler is as doubtful of the virtues of boot-leather as I am of the value of expectorants.

* * *

Let it not be said that a despairing cry in these columns (Feb. 18, p. 323) went unanswered. These innumerable calls to the front door by people who merely want to know the surgery hours and seem blind to notices on the gate can be stopped if one is willing to spend about £30. This is the cost of a microphone-loudspeaker system attached to the front door, with a relay microphone in each living-room. This system has worked extremely well at a colleague's house, once the patients got over the shock of a bodyless voice answering their ring at the door. It is worth £30 just to talk to a night caller shivering on the mat without moving from one's bed; though of course one always has to get out in the end.

* * *

The sanitary inspector, like the policeman, may well claim that his lot is not a happy one; it would be difficult, I imagine, to find romance or glamour in the abatement of offensive trades and the removal of nuisances. But there are compensations in his work which seem to foster the more prosaic and solid virtues, for in my experience sanitary inspectors as a class have more than their fair share of respectability, tact, reliability, and common sense. Judging by the following letter, received recently at the Health Department, the S.I. must also possess patience and courage.

> Dear Sir,
>
> Lavatory made up at above address. Sorry to cause you this trouble. Will leave back door open on Friday morning. Just call dog by name Rex and pet him for a few minutes and he is all yours.
>
> Yours truly, ...

I remember, as a student, being conducted through the horrors of tenement slumdom by an admirable member of the sanitary staff, as part of the course in—of all things—Public Health. The life of the poor was public enough, but there was little or no health, and the more cynical members of the class altered its designation to Public Filth. It was then I found out that the inspector was expected not only to cope with dampness, defective drains, and dry rot but also to discourage drunkenness, debauchery, and divorce, on information supplied chiefly by anonymous letters. Adulteration and adultery were all in the day's "darg," and the annals of the poor were not so short and simple as Gray thought.

But a very large part of the work of the S.I. is made up of "made up" lavatories, and he may agree with Mrs. Humphrey Ward when she says "In my youth people talked about Ruskin. Now they talk about drains." Here is a sample of the many letters the S.I. gets on this perennial subject.

> Sir,
>
> Please will you send a man down to look at the lavatory being made up. Wife in bed ill, cannot do with smell and having five children kindly oblige,
>
> Yours . . . .

More excretory unrest can be seen in the following:

> Dear Sir,
>
> May I draw your attention to the Ladies Toilet in the Main Street, it is used very often but after leaving that we have no other till B——d and the next N——n. I have a baby of three months so I have to use my pram as the baby cannot be carried or travel by bus. When I have come in town for my National milk, etc., my walk back is a very good stretch and many times have been in need of a Toilet very badly and felt really ill by holding myself, which is not very good for Man or Woman. We have many lovely walks but always the snag of no Toilet. I would like you to put it in front of the Health Committee and ask them to study a while how many the Gentlemen have on the roads to the Ladies. I would be very obliged and it would make many a Lady happy to know the Health Department think about them.
>
> Yours truly . . . .

The sanitary inspector may also have to brush up his psychiatry.

> Dear Sir,
>
> Will you please see to the way the maniac at No. 75 The Crescent, is acting. She is a proper nuisance to the street what with shouting and insulting strangers passing by and now she has started keeping pigeons in her bedroom, also hens and ducks and we think it about time she was put in her place.
>
> We remain,
>
> The People Round About.

In this case, however, it would be the medical practitioner who might empty some dull opiate to the drains.

* * *

My Missus (to George, aged 7): "No, no. It's 'a pocket full of posies,' not a pokker fuller posies. What are 'posies,' anyway?"

George (rather to my surprise): "Flowers, aren't they? But why does it end with afishoo?"

M.M. (inspired): "I don't know. Perhaps it's about hay-fever."

Letters to the Editor

RESISTANT STAPHYLOCOCCI

SIR,—I have read with interest the reports by Rountree and Thomson[1] and of Dr. Mary Barber and her associates[2] concerning the parasitisation or infection of staff and patients in the Royal Prince Alfred Hospital, Sydney, and St. Thomas's Hospital, London, with strains of penicillin-resistant *Staphylococcus aureus*.

I would judge from observations made in the United States that the incidence of penicillin-resistant strains of this organism in infections is definitely increasing. This poses a problem in therapy. While many of the penicillin-resistant strains are sensitive to streptomycin, these may rapidly become resistant to this antibiotic in the course of therapy. Also, the treatment of serious infection with this latter antibiotic is not without risk from the rather frequent toxic reactions.

Our experience has convinced us that 'Aureomycin' is a highly effective antibiotic agent in staphylococcal infection. Hitherto its toxic effects, other than nausea, vomiting, and looseness of the bowels, have been minimal. Because of its effectiveness in relatively modest doses and its lack of toxicity, it is our belief that aureomycin is now the antibiotic of choice for the treatment of staphylococcal infection. I feel that physicians would do well to keep this point in mind, because only too frequently large amounts of penicillin are wasted in attempts to control a staphylococcal infection which would respond promptly to therapy with aureomycin.

TRICHLORETHYLENE IN OBSTETRICS

SIR,—Recently we witnessed one of the regularly recurring instances of lay interest in obstetrical analgesia. This coincided with correspondence in the medical press on the same subject; and the matter was finally referred to a committee. Meanwhile it appears to me that there is a general impression that we have but to await the invention of the perfect apparatus so that the midwife can administer trichlorethylene, instead of gas-and-air, and the problem of obstetrical analgesia will be finally solved. May I make a plea that gas-and-air shall not be too readily discarded?

When properly administered, gas-and-air gives a good degree of analgesia for the greater part of the average labour. When it fails adequately to cover the actual birth, it does so for one or more of the following reasons: (*a*) the administration has not been thoroughly explained to the patient (the extent of success with gas-and-air is frequently in direct ratio to the attention given to its administration); (*b*) however well the administration is supervised, gas-and-air, per se, is not always adequate for this stage of labour; (*c*) the strength of the analgesic agent has remained fixed while the strength of the pain stimuli has been steadily increasing, so that after some time the patient may acquire quite a fair degree of tolerance.

What is the case for replacing this régime by the inhalation of a fixed concentration of trichlorethylene? I believe that trichlorethylene is an outstandingly good analgesic for midwifery, its optimum usefulness being towards the end of the second stage when it frequently gives good relief where gas-and-air has failed to do so. But I also believe that it has two disadvantages. The first is that when it is given as the sole inhalational agent and at a constant strength, the patient can acquire, as in the case of gas-and-air, sufficient tolerance to render it not quite adequate for the delivery. On the second disadvantage I speak with great caution. There are so many factors influencing the course of labour that it is very difficult to judge accurately and justly the effects of one drug. Nevertheless I have gained the definite impression that where trichlorethylene has been inhaled over a long period, the uterine action sometimes tends to become increasingly sluggish. On the other hand, I have never had reason to regret reserving trichlorethylene for the last part of labour and then giving it in adequate strength.

Are we, then, going to gain much from this possible switch-over? It has always seemed to me that we are rather optimistic to expect that the pains of the various phases of labour, varying as they do not only in intensity but also in nature and in the way in which they impinge on consciousness, shall be adequately covered by an unvarying concentration of one drug. Surely the answer lies in the correctly timed application of both of these valuable drugs.

I would suggest as the ideal, that the patient delivered by a midwife should be given gas-and-air, starting as the first stage nears its end, and continued until the head is starting to pass over the perineum. Trichlorethylene should then be substituted, given by an inhaler the safety of which is determined by limitation of the total quantity of the drug as well as by constancy of concentration. Thus we should realise the advantages of each drug without incurring the shortcomings of either.

Objections may be raised on two grounds: difficulty of transport, and lack of simplicity. The former has been largely answered by the introduction of light-weight cylinders: a portable model working on the jet-and-venturi system, which I have found very satisfactory, weighs just on 20 lb. when fitted with a 100 gallon light-weight cylinder. As regards lack of simplicity, I feel that this disadvantage will be outweighed by the advantages to the patient.

London, W.8.

G. C. STEEL.

INCIDENCE OF PEPTIC ULCER

SIR,—Substantial differences in the proportions of duodenal to gastric ulcer are being reported in perforation series from different parts of the country: for instance, 6½ : 1 in Glasgow,[1] almost 9 : 1 in Newcastle,[2] and about 3 : 1 in London.[3] There is no obvious explanation for these discrepancies, and so little is known of the causes of ulcer and its increase in recent years that no clue should be neglected. We are therefore following it up in a small investigation.

The Ministry of Food have kindly agreed to send a communication from the Medical Research Council to the certifying doctor for each occasion on which priority milk and/or eggs were claimed on form R.G.50, class 1 (D), in Glasgow, Newcastle, Willesden, and Acton during a period in December, 1949. This communication will contain an explanatory covering letter, a form for entering facts about the patient, such as sex, age, and situation of ulcer, and a stamped addressed envelope for its return to us. When the information is analysed it should be possible for the first time to work out rates for different types of ulcer in different areas of the country, and to know whether some areas have a particularly high or low incidence of gastric or duodenal ulcer.

A serial-number system will be used whereby the confidential nature of medical information will be faithfully preserved. No names will pass from the doctors to us; no information will be passed back by ourselves to the Ministry of Food. We have consulted the chairman of the central ethical committee of the British Medical Association, and he assures us that there can be no ethical objection to the completion of the forms.

[3] Jones, F. A., Parsons, P. J., White, B. *Ibid*, Jan. 28, p. 211.

We hesitate to trouble doctors, and in particular general practitioners, with yet another form to fill, but there is no other practicable way of getting this necessary information. National Insurance certificates cannot help us since they are concerned with absence from work among the insured section of the population. We should therefore be most grateful for the assistance of practitioners in this inquiry.

PURIFICATION OF VACCINE LYMPH

SIR,—In his letter of Feb. 18 Dr. Rao compares the phenol and chloroform-vapour processes for the purification of vaccine lymph, and concludes that the latter method when used in the manner described by him is much quicker while being efficacious and harmless.

When using the phenol method, however, he added "phenol in a concentration of 0·5% to the diluent—a 50% solution of glycerin in water." The final concentration of phenol was therefore presumably less than 0 5%. He stored the mixture at − 11°C. It is known that glycerol reduces the bactericidal action of phenol. If Dr. Rao had tried the method described by me,[1] which involves the addition of two volumes of 1% phenol to the crude vaccine pulp followed by 48 hours' incubation at 22°C, he would have found the reduction in the bacterial content to be greater after this period than that achieved with chloroform vapour; the reduction in viral potency of the lymph is negligible. The final concentration of phenol is reduced to 0·4% by the addition of glycerol.

We have considerable experience of the chloroform-vapour process, which, as Rao mentions, was developed by Green[2] in these laboratories. Our experience of the relative simplicity and efficacy of the phenol method, which avoids the necessity of bubbling chloroform vapour through the lymph and then removing it with a stream of sterile air, led us to abandon the chloroform-vapour process in 1941. The antiseptic action of a final concentration of 0 4% phenol in the lymph is also of value.

The Lister Institute of Preventive Medicine,
Elstree, Herts.

SUPERINFECTION IN TUBERCULOSIS

SIR,—We read with great interest your report (Jan. 28) of the British Tuberculosis Association's debate on infection. We believe that the experience of recent years with sensitivity studies on streptomycin-treated cases of pulmonary tuberculosis is important in evaluating the rôle of superinfection in tuberculosis.

Streptomycin has been used at this hospital for over three years. The cases in which resistance of the organisms to this antibiotic developed during or after treatment have not been separated from other positive cases on the hospital wards. Despite this intimate exposure, in none of the patients (368) was initial resistance of the bacilli to streptomycin encountered—which certainly would not have been the case if superinfection played a major part in the development of tuberculosis. Furtos's[3] experience with 385 cases is identical with ours.

Infection of hospital employees with streptomycin-resistant bacilli could be expected if superinfection were of major importance. Three of our employees have developed active pulmonary tuberculosis during the past three years. One of them, an initially tuberculin-negative, recently employed, young man, was infected with streptomycin-resistant organisms (this case will be published). This was, however, a case of primary tuberculosis. The two others were middle-aged, long-time employees who developed reinfection-type disease; and their very favourable personal and environmental circumstances have not changed for many years, except for one factor—their recent exposure to patients harbouring streptomycin-resistant bacilli. Despite this, the organisms isolated from the sputa of these two men were found to be sensitive both to streptomycin and to *para*-aminosalicylic acid.

The existence of superinfection is beyond any doubt; its relative importance, however, is a different question. The above experience seems to speak against a great practical significance of superinfection in tuberculosis.

Veterans Administration Hospital,
Walla Walla, Washington.

L. S. ARANY
W. G. LEWIS.

THE FORGOTTEN SWAB

SIR,—As a theatre sister in a provincial teaching hospital, I was interested to read the leading article in your issue of Feb. 18.

May I, as a result of personal experience, put forward the following suggestions. Whilst thoroughly endorsing all you say, I feel that there are still one or two ways of making quite sure that the swab-check is thoroughly foolproof. In the case of intraperitoneal operations, the point at which swabs should be checked is very evident —it is at the commencement of closure of the peritoneum. There are, however, many major operations where the point for swab-checking is not so evident, particularly in bladder and prostatic surgery. It would seem that the best moment for swab-checking in these operations is on closing the bladder or prostatic capsule. However, even after that point there are still many crevices into which a swab might be tucked and overlooked. Therefore I think that in any operation, no matter at what stage the swabs are first checked, no swab should be removed from the swab-horse until the surgeon is actually inserting the skin-sutures; and at this point the nurse in charge of the case should again ascertain that they are correct. The nurse in charge of the case should always be asked by the floor-nurse if she can remove the swabs from the theatre; the over-anxious floor-nurse, often new to theatre technique, often tends to remove the swabs after the first check, not realising that there is still a possibility of one becoming mislaid.

Another source of error is encountered when a surgeon using a tiny gauze swab on a hæmostat, for blunt dissection, encounters sudden, unexpected hæmorrhage. The swab is released from the hæmostat, which is used to check the hæmorrhage, and in the heat of the moment the very existence of the tiny swab is forgotten by all except the nurse in charge of the case; her duty is to remove it if easily accessible, or to remind the surgeon, when the hæmorrhage is controlled, if she cannot find it.

I regard a swab-book as absolutely essential in every theatre, and feel that even in the most unlikely cases swabs should be checked; in a radical mastectomy I have known a large swab, saturated with blood, to be almost overlooked as it nestled in the dissected axilla.

As you state, it does seem surprising that instruments can be left inside a patient. Occasionally, however, a patient requires an emergency transfusion during an operation. Hæmostats are hurriedly removed from a spare set in the instrument cupboard for use on the "drip" trolley. These hæmostats are almost invariably identical with those used for the operation in progress; and at the end of the operation, it has been known for one of these hæmostats to be counted in with those used for the operation. It is not until the spare sets of hæmostats are counted, perhaps that evening or even next morning, that it is realised that one is missing.

---

1. McClean, D. *Lancet*, 1949, ii, 476.
2. Green, A. B. Report of the Medical Officer, Local Government Board, 1900–01, p. 639; *Ibid*, 1901–02, p. 575; *Ibid*, 1902–03, p. 659.
3. Furtos, N. C., Doane, E. A. *J. Amer. med. Ass.* 1949, 140, 1274.

Even then, it may not be understood how this occurred ; and all the patients operated on that day have to be X-rayed. Thus time and money are wasted. This may be avoided by keeping a permanent set of intravenous transfusion instruments in which the hæmostats differ from those in general use in the theatre.

In conclusion, I never “ take ” an operation without the coroner's court at the back of my mind—a pessimistic outlook, perhaps, but it makes me careful, and it helps me to teach my staff to be careful, too.

Birmingham. PATRICIA KENT.

THE CARNAGE ON THE ROADS

SIR,—I read with interest Dr. Learoyd's article last week. The remedy is to allow anyone to drive ; but anyone involved in an accident must come before a special court (Road Fund Court) for a permit to drive. Thus people would drive in such a manner as to avoid accidents and would learn how to avoid accidents before driving. Incidentally compulsory third-party insurance *causes* accidents.

Derby. F. W. SCHOFIELD.

THE BODY-IMAGE IN NEUROLOGY

SIR,—I would like somewhat to extend the subject of Dr. Macdonald Critchley's article last week on the part played by the body-image in the brain. I suppose that abdominal visceral activity was originally largely under the control of the primitive brain and is still affected by emotional disturbance in the cerebral cortex (of the neocerebrum) through the corticothalamic connections. I have lately written an article on retrograde peristalsis and vomiting of fæces, enemata, and suppositories in functional nervous conditions.[1] Such disturbances may be, I think, regarded as greatly exaggerated equivalents of ordinary so-called hysterical vomiting, induced by disturbances (especially emotional disturbances) in certain individuals under special conditions. In fact, by a stretch of one's imagination, one might say “ induced by emotional disorders of the body-image in the cerebral cortex.”

London, W.1. F. PARKES WEBER.

CONTROL OF TUBERCULOSIS

SIR,—In his letter of Feb. 18 Dr. Ellman ably stated the gravity and urgency of the national tuberculosis crisis, and indicated some of the means by which it may be fought. If these are properly used there are enough beds, enough physicians, enough surgeons ; everything fails with the lack of nurses. What is the cure ?

The late Miss Nightingale put a stamp of military organisation and Victorian dedication upon nursing which still informs, if not inspires, the Royal College of Nursing, and is a disastrous misfortune in 1950. It is perfectly obvious that young trainees, under 21, to whom hospital authorities stand more or less *in loco parentis* must live under reasonable supervision and discipline ; it is equally clear that just so long as professional women of adult status are required to live like medieval nuns in a Paraclete, any girl in her right mind will become a typist instead and have a bed-sitter in Bayswater. I know a hospital where, until recently, wardmaids had separate bedrooms but sisters “ doubled up.” Enough of the latter have now left to solve this problem. *Of course* nurses must be allowed, and encouraged, to live out if they wish ; and the concern of matrons and hospital committees should begin and end with their nursing efficiency.

If you want people, whether nurses or miners, to do jobs you cannot, or will not, do yourself (or let your daughter do), you must pay them enough to make it worth while—not appeal to their sense of “ vocation ” to do it cheaply. The salaries, and derisory “ bonus,” to be paid to tuberculosis nurses show just how far the country is from dealing with this horrible, and growing, spectre.

London, N.W.3. GEOFFREY FLAVELL.

RESPIRATORY OBSTRUCTION

SIR,—I read with interest Dr. Boyd's article of Feb. 18.

I have had a young hæmophiliac who was admitted to hospital with moderate respiratory obstruction due to an effusion of blood behind the mylohyoid muscle. The picture resembled Ludwig's angina. Blood could be seen through the mucous membrane of the undersurface of the tongue. The respiratory obstruction became more distressing and tracheotomy was contemplated. However, improvement rapidly followed the transfusion of a pint of fresh blood.

The patient, a mental defective, is in the habit of rocking his teeth until he loosens them and probably started the hæmorrhage in this way.

Grays, Essex. R. N. HERSON.

SIR,—Dr. Boyd's article reminds me of a case I was asked to see some two years ago at the Cumberland Infirmary.

A middle-aged woman was admitted *in extremis* to a medical ward. She was unconscious, and her colour was grey. She was obviously suffering from severe respiratory obstruction, and despite full exertion of her accessory muscles of respiration she was unable to achieve any discernible respiratory exchange.

There were no external signs to indicate the cause of obstruction. Inspection of the larynx with a Macintosh laryngoscope revealed that the cords opened normally during the expiratory phase but appeared to close completely during attempted inspiration. An endotracheal tube with analgesic lubricant was easily passed, through the nose, during expiration, and the patient's condition improved rapidly. In about half an hour she was apparently normal, and soon afterwards the tube was removed without a recurrence of spasm.

The patient gave a history of several previous attacks of spasm, but none had been so severe as this. After full investigation the attacks were attributed to pressure on the recurrent laryngeal nerve by very extensive dilatation of the œsophagus.

This case, I think, offers further evidence of the value of timely intubation as an alternative to tracheotomy.

FRANK L. ROBERTSHAW
Royal Hospital, Sheffield. Senior Anæsthetic Registrar.

APPROACH TO THE UPPER THORACIC SYMPATHETIC GANGLIA

SIR,—I agree with Mr. McCurrich (Feb. 4) that honour should be given where it is due. In regard to the anterior approach to the upper thoracic sympathetic chain the first name that should come to mind is that of Prof. E. D. Telford, who has enriched the field of sympathetic surgery more than any other man in Britain. He was the first to carry out section of the upper thoracic chain, as opposed to stellate ganglionectomy, and so avoided the disfiguring Horner's syndrome while securing an equally good sympathetic release in the hand. Moreover, his various modifications have rendered the operation by the anterior approach one of the easiest and safest of all interventions on the sympathetic chain. I know that he has done over 300 of these operations without mishap of any kind, and I have myself done his operation on many patients. It can be done bilaterally at one sitting, and patients have gone home four days later free from pain and with their wounds healed. The posterior approach causes more upset to the patient, and those who have had Telford's operation on one side and Smithwick's on the other state that the latter is much more painful and for a longer period.

---

[1] *Med. Pr.* 1950, 223, 120.

In view of such results I cannot regard the peraxillary route, advocated by Mr. Atkins (Dec. 17 and Jan. 14) as anything but a retrograde step. Why should one, without adequate reason, expose a patient to the risks of an opened pleura and to the prolonged and painful convalescence inevitable to resection of rib? By the anterior approach the chain can always be cut below the 3rd thoracic ganglion, and the sympathetic release in the arm is at least as complete as can be secured by more tedious and risky routes.

Manchester. H. A. HAXTON.

POSTOPERATIVE PARALYSIS IN THE UPPER EXTREMITY

SIR,—I have noticed with interest your leading article of Jan. 21 and the correspondence concerning brachial palsy following operations, chiefly gynæcological and on the gall-bladder.

I myself first met with this condition in about 1922, when open prostatectomy by the transvesical route was first being extensively practised. In these cases the patient was held on the table by the usual shoulder-rests, and the legs were commonly flexed at the knee. None the less, inasmuch as a considerable tilt of the table into the Trendelenburg position was often required, the conditions were favourable to the production of injury to the lower cord of the brachial plexus. We had several such cases at St. Peter's Hospital, notably affecting the ulnar nerve. It appeared to me that the mechanism was simply that, the shoulder-girdle being fixed, the tilting of the table caused the conical thorax to slide up into the shoulder-girdle as a result of gravitation, and it thus compressed the plexus.

I therefore, in 1925, got Messrs. Allen & Hanburys to design for me what have since been called the "St. Peter's pattern iliac-crest supports," or "pelvic rests." These fix on to the St. Bartholomew's table manufactured by Allen & Hanburys, and support the patient when tilted by fixation against the iliac crests. Since that time I have never seen another case of this condition, either at St. Peter's, or at the Royal Masonic Hospital, or at the London Clinic, where these appliances are used. I learned afterwards that Mr. J. B. Macalpine had designed a similar method of supporting the patient when a head-down position is required.

A little knack and training are needed by the theatre orderlies to fix the supports correctly; but this is quickly learned, and when correct the position is absolutely secure. I myself was, for purposes of a catalogue, photographed on the table in the extreme Trendelenburg position, held by these supports only and without my legs being dropped. It was an interesting experience, and I recommend it to all surgeons and anæsthetists who are not trained gymnasts and therefore are not in the habit of standing on their heads. The cerebral congestion produced is, of course, considerable, and ever since then I have been vary cautious in the amount of tilt that I permit for bladder and prostatic operations, particularly in elderly patients—not because there is any risk of slipping or of nerve injury, for, as I say, with the iliac supports properly adjusted, this is quite impossible, but because I think the Trendelenburg position throws a great strain upon the circulatory arrangements of elderly people. There is of course also to be remembered the compression of the diaphragm by the abdominal viscera gravitating towards the thorax.

London, W.1. R. OGIER WARD.

SIR,—I have read with interest the various articles and letters on this subject, and I would like to support Mr. Lee's contention (Feb. 11) by quoting two cases which I anæsthetised last year.

In the first case the lesion (a left arm palsy) occurred in an elderly woman following Smith Petersen nailing for a pertrochanteric fracture of the left femur. The anæsthetic consisted of intermittent thialbarbitone and gas-and-oxygen, and no relaxant drug was used. During the operation, in order to keep the left arm out of the way of both the surgeon and the portable X-ray machine, it was hyperabducted, flexed, and externally rotated, and was anchored in this position to the top of the Hawley table.

In the second case the lesion (a right arm palsy) occurred in a middle-aged man following partial gastrectomy. The anæsthetic consisted of thiopentone, curare, and cyclopropane. During the operation, in order to give the surgeon more room, the right arm was hyperabducted whilst fixed to an arm-board in extension and external rotation.

It would appear that relaxants and the gall-bladder and Trendelenburg positions of themselves are not important factors in the production of postoperative brachial palsy, but rather the position of the arm itself in hyperabduction and external rotation, particularly in those patients who have a post-fixation brachial plexus.

Hull. W. N. ROLLASON.

FLATULENCE IN INFANCY

SIR,—In his letter of Feb. 11, Dr. Tizard suggests that the perambulator is in part responsible for windy colic in the baby. May I suggest that the clock also is often to blame? It helps to maintain an arbitrary duration for the feed, and interval between feeds, which may not be suited to the temperament and appetite of the individual baby.

I have found that the technique used in dislodging an air-bubble from a syringe is useful when applied to my babies; if tapping in the vertical position will not release the bubble, a beautiful belch will often result when the vertical is resumed after half a minute in the prone position.

London, W.8. NORMA MACLEOD.

REGISTRARS

SIR,—It seems to me that senior registrars in non-teaching hospitals stand practically no chance of obtaining a consultant appointment. Yet in many ways the experience gained in a good non-teaching hospital fits a man better for consultant status than experience gained solely in teaching hospitals.

Most senior registrars, and many registrars, in non-teaching hospitals are doing consultant work and taking great responsibility; but when they come to be considered for a consultant post the stigma of the non-teaching hospital is upon them—they do not fit the conventions of the selection committee. Should they apply for a consultant post at the hospital where they are working, the chiefs and those who know them will have a minority representation on the selection board. Should they apply for a consultant appointment in the region in which their hospital lies, their chiefs will often have no representation at all on the selection board. On their own regional hospital board and regional selection board most of the medical representatives will be from hospitals completely independent of the regional board. These registrars will be unable to rely on the fruits of patronage; these are for others. Should they apply for a consultant post in another region, they will normally have no celebrity to back them, though their chiefs may be good and capable doctors.

Registrars should be appointed by a committee representing equally the hospital concerned, the other regional hospitals, and the teaching hospital of the region; the casting vote should be with the consultant under whom the registrar will work.

Many registrar posts are being made where the need is not for more registrars but for more consultants. An attempt is being made to get work on the cheap. Before the health service started, it was estimated that the number of consultants should be at least twice as great as before the war; and the large number of ex-Service postgraduate appointments was based on this. Now

Even then, it may not be understood how this occurred; and all the patients operated on that day have to be X-rayed. Thus time and money are wasted. This may be avoided by keeping a permanent set of intravenous transfusion instruments in which the hæmostats differ from those in general use in the theatre.

In conclusion, I never "take" an operation without the coroner's court at the back of my mind—a pessimistic outlook, perhaps, but it makes me careful, and it helps me to teach my staff to be careful, too.

Birmingham. PATRICIA KENT.

THE CARNAGE ON THE ROADS

SIR,—I read with interest Dr. Learoyd's article last week. The remedy is to allow anyone to drive; but anyone involved in an accident must come before a special court (Road Fund Court) for a permit to drive. Thus people would drive in such a manner as to avoid accidents and would learn how to avoid accidents before driving. Incidentally compulsory third-party insurance *causes* accidents.

Derby. F. W. SCHOFIELD.

THE BODY-IMAGE IN NEUROLOGY

SIR,—I would like somewhat to extend the subject of Dr. Macdonald Critchley's article last week on the part played by the body-image in the brain. I suppose that abdominal visceral activity was originally largely under the control of the primitive brain and is still affected by emotional disturbance in the cerebral cortex (of the neocerebrum) through the corticothalamic connections. I have lately written an article on retrograde peristalsis and vomiting of fæces, enemata, and suppositories in functional nervous conditions.[1] Such disturbances may be, I think, regarded as greatly exaggerated equivalents of ordinary so-called hysterical vomiting, induced by disturbances (especially emotional disturbances) in certain individuals under special conditions. In fact, by a stretch of one's imagination, one might say "induced by emotional disorders of the body-image in the cerebral cortex."

London, W.1. F. PARKES WEBER.

CONTROL OF TUBERCULOSIS

SIR,—In his letter of Feb. 18 Dr. Ellman ably stated the gravity and urgency of the national tuberculosis crisis, and indicated some of the means by which it may be fought. If these are properly used there are enough beds, enough physicians, enough surgeons; everything fails with the lack of nurses. What is the cure?

The late Miss Nightingale put a stamp of military organisation and Victorian dedication upon nursing which still informs, if not inspires, the Royal College of Nursing, and is a disastrous misfortune in 1950. It is perfectly obvious that young trainees, under 21, to whom hospital authorities stand more or less *in loco parentis* must live under reasonable supervision and discipline; it is equally clear that just so long as professional women of adult status are required to live like medieval nuns in a Paraclete, any girl in her right mind will become a typist instead and have a bed-sitter in Bayswater. I know a hospital where, until recently, wardmaids had separate bedrooms but sisters "doubled up." Enough of the latter have now left to solve this problem. Of course nurses must be allowed, and encouraged, to live out if they wish; and the concern of matrons and hospital committees should begin and end with their nursing efficiency.

If you want people, whether nurses or miners, to do jobs you cannot, or will not, do yourself (or let your daughter do), you must pay them enough to make it worth while—not appeal to their sense of "vocation" to do it cheaply. The salaries, and derisory "bonus," to be paid to tuberculosis nurses show just how far the country is from dealing with this horrible, and growing, spectre.

London, N.W.3. GEOFFREY FLAVELL.

RESPIRATORY OBSTRUCTION

SIR,—I read with interest Dr. Boyd's article of Feb. 18.

I have had a young hæmophiliac who was admitted to hospital with moderate respiratory obstruction due to an effusion of blood behind the mylohyoid muscle. The picture resembled Ludwig's angina. Blood could be seen through the mucous membrane of the undersurface of the tongue. The respiratory obstruction became more distressing and tracheotomy was contemplated. However, improvement rapidly followed the transfusion of a pint of fresh blood.

The patient, a mental defective, is in the habit of rocking his teeth until he loosens them and probably started the hæmorrhage in this way.

Grays, Essex. R. N. HERSON.

SIR,—Dr. Boyd's article reminds me of a case I was asked to see some two years ago at the Cumberland Infirmary.

A middle-aged woman was admitted in extremis to a medical ward. She was unconscious, and her colour was grey. She was obviously suffering from severe respiratory obstruction, and despite full exertion of her accessory muscles of respiration she was unable to achieve any discernible respiratory exchange.

There were no external signs to indicate the cause of obstruction. Inspection of the larynx with a Macintosh laryngoscope revealed that the cords opened normally during the expiratory phase but appeared to close completely during attempted inspiration. An endotracheal tube with analgesic lubricant was easily passed, through the nose, during expiration, and the patient's condition improved rapidly. In about half an hour she was apparently normal, and soon afterwards the tube was removed without a recurrence of spasm.

The patient gave a history of several previous attacks of spasm, but none had been so severe as this. After full investigation the attacks were attributed to pressure on the recurrent laryngeal nerve by very extensive dilatation of the œsophagus.

This case, I think, offers further evidence of the value of timely intubation as an alternative to tracheotomy.

FRANK L. ROBERTSHAW
Royal Hospital, Sheffield. Senior Anæsthetic Registrar.

APPROACH TO THE UPPER THORACIC SYMPATHETIC GANGLIA

SIR,—I agree with Mr. McCurrich (Feb. 4) that honour should be given where it is due. In regard to the anterior approach to the upper thoracic sympathetic chain the first name that should come to mind is that of Prof. E. D. Telford, who has enriched the field of sympathetic surgery more than any other man in Britain. He was the first to carry out section of the upper thoracic chain, as opposed to stellate ganglionectomy, and so avoided the disfiguring Horner's syndrome while securing an equally good sympathetic release in the hand. Moreover, his various modifications have rendered the operation by the anterior approach one of the easiest and safest of all interventions on the sympathetic chain. I know that he has done over 300 of these operations without mishap of any kind, and I have myself done his operation on many patients. It can be done bilaterally at one sitting, and patients have gone home four days later free from pain and with their wounds healed. The posterior approach causes more upset to the patient, and those who have had Telford's operation on one side and Smithwick's on the other state that the latter is much more painful and for a longer period.

Obituary

GEORGE RICHARDS MINOT

A.B., M.D., S.D. HARVARD, F.R.C.P., F.R.C.P.E.

George Minot died at his home in Boston last Sunday. History will always remember him as the man who received the Nobel prize for his discovery of the cure for pernicious anæmia, and as one of the company of great physicians—Harvey, Jenner, Addison, Harvey Cushing, Thomas Lewis—whose work was the starting-point for a sudden leap forward in our understanding of disease. Until Minot and Murphy published in 1926 a short paper suggesting that patients with pernicious anæmia could be relieved of their anæmia by eating large quantities of liver, hæmatology had been a subject that chiefly interested those morphologists who were fond of devising elaborate tables describing the slightly apocryphal development of the blood-cells. Minot's work, linked with that of Whipple at Rochester, stimulated a new physiological approach to the problems of hæmopoiesis, and through them to the closely related problems of gastro-intestinal function. Not content to cure his patient, he went on in collaboration with William Castle to analyse the significance of his findings, to express as far as he could the ætiology of the disorders of hæmopoiesis, and to devise quantitative measures for assessing the response of the body to the newly discovered hæmopoietic factors. His use of the reticulocyte response will always be a fine example of the value of accurate measurement in checking clinical assessment.

New York Times

J. V., who worked in the Thorndike Laboratory in 1929–30, writes: "His standards of work were, one often felt, unattainable. Two days before I was to read a paper at Atlantic City I showed him the graphs I was to use. A blue pencil went through them all because of small imperfections of style. Again and again he would go through the same paper with his junior staff, writing and rewriting in order to get the meaning crystal clear, the English to his liking. In the same way he rehearsed us all with much personal advice before we read a paper to a learned society. Whatever work we have done since has instinctively been measured against his standard. Once a week the whole laboratory staff at the Thorndike used to meet and discuss research problems; usually if Minot was there we ended up in the ward to see how the particular patients were 'getting along' or to clarify some point in their history that seemed to him relevant. He always said that it was a constant study of his patients' histories that first led him to suspect the efficacy of liver. I have beside me a great file of his letters, comments on work both here and in the States, news of his holidays on the coast of Maine, of the flowers and birds in his garden, and of American politics. During the war years these letters came frequently and always in the worst moments, full of quick understanding of our problems and a warm anxiety to help, but bringing also news of a saner world which was in itself a tonic.

"The vastly expanding literature, in every language, on problems associated with hæmopoiesis, in journals devoted to biochemistry, biophysics, medicine, and pharmacology, are a measure of Minot's gift to his own and succeeding generations. To those of us who had the privilege of working with him, he will always remain a great scholar, a great gentleman, a most beloved physician, and a friend."

A further tribute comes from L. S. P. D., who recalls how young graduates of every nationality journeyed to Boston to obtain the training and mental stimulation which were inseparable from an association with Minot, and speaks of the human qualities of modesty, courtesy, and kindliness, with which he was so richly endowed.

George R. Minot was born at Boston in 1885, the son of Dr. James Minot. He took his degree in arts from Harvard University in 1908 and graduated in medicine in 1912. For a time he held a resident appointment at the Johns Hopkins Hospital in Baltimore, and later he held a research fellowship in the physiological laboratory of the medical school. In 1915 he returned to Boston to join the staff of the Massachusetts General Hospital. In 1921 he was found to be suffering from diabetes and he became seriously ill, but the discovery of insulin by Banting and Best in 1922 came in time to restore him to full-time work. In 1928 he was appointed to the chair of medicine at Harvard, which he held till he retired in 1948. A Nobel laureate of 1934 and a fellow of the Royal Colleges of Physicians of London and Edinburgh, Dr. Minot had been honoured by his colleagues all over the world. He had received the Kober gold medal of the Association of American Physicians, the Mickle fellowship of the University of Toronto, the Cameron prize of the University of Edinburgh, the Moxon medal of the Royal College of Physicians, the John Scott Medal of the City of Philadelphia, and the gold medal of the Humane Society of Massachusetts.

He married in 1915 Miss Marian Weld, who survives him with a son and two daughters.

SAMUEL ERNEST WHITNALL

M.A., D.M. OXFD, F.R.S.(C.)

As we announced last week, Dr. S. E. Whitnall, formerly professor of anatomy at McGill University, Montreal, and the University of Bristol, died on Feb. 19, at the age of 73.

Samuel Ernest Whitnall was born in Lancashire on March 30, 1876. He received his early education at Radley College, Abingdon, and Owens College, Manchester. In 1897 he went up to Magdalen College, Oxford; and he took his clinical training at St. Thomas's Hospital, London, qualifying in 1908. The next year he graduated M.D.

From 1908 to 1914 he was university demonstrator of human anatomy at Oxford. During the years of the first world war he served, as a captain, with the R.A.M.C. in this country and in France; and in 1918 he was administrator of the Orthopædic (Military) Hospital, Oxford. In 1919 he went to Canada as Robert Reford professor of anatomy at McGill University. He returned to this country to occupy, in 1935, the chair of anatomy at Bristol University; and he retained this appointment until he retired in 1941.

"S. E. Whitnall," writes J. S. B., "was perhaps best known to anatomists and surgeons for his contributions to ophthalmological anatomy. During his early years as a demonstrator of human anatomy at Oxford, he published a number of papers on the topographical anatomy of the orbit. These established his reputation as an expert on this region of the human body which was further enhanced by the appearance in 1921 of his monograph *The Anatomy of the Human Orbit.* This book quickly became a standard work of reference both in this country and in Canada and the U.S.A.

"Whitnall's experiences as a teacher of anatomy in Oxford and McGill University prompted him to set down his ideas on the relation of anatomy to the medical curriculum in a book called *The Study of Anatomy.* This book was intended to be read by undergraduate students as an introduction to their preclinical studies but contains much upon which teachers of the subjects concerned could afford to ponder. The views expressed are as true in the present days of an overcrowded medical curriculum as when they were first written in 1923.

"Whitnall excelled as a lecturer. He was a master of the spoken word; his ideas were put forward in simple form with the emphasis always on what he regarded as fundamental, while the whole was enlivened by the flashes of his scintillating wit. Only those who knew him understood how much time and care were devoted to the preparation of these lectures.

"He was considerate and kind to his subordinates, allowing them much freedom in working out their own methods of teaching; but he always insisted on a high sense of their duty towards the student."

Professor Whitnall married Zoë, daughter of the late C. C. Wyllie. There were two sons and one daughter by the marriage.

even the *Times*[1] has commented on the apparent haphazard appointment of consultants; there is no doubt that an inadequate number of consultant posts is being made. Here the interests of the Treasury and of many established consultants coincide, though for different reasons: the Treasury must cut the cost, and the established consultant does not want more competition. Furthermore, the Ministry of Health has not been overactive in trying to secure an agreed basis for the establishment of consultants.

To the Spens Committee the registrar was a trainee specialist; but now the name has been changed and with it the status. A registrar can be employed for all manner of purposes: a trainee specialist cannot be so cynically used. This twisting of nomenclature has also taken place with the compound term "consultants and specialists"; the specialist half has been quietly dropped. The average trained man does not expect consultant status at the age of 32, but he does expect specialist status.

There is no hope of obtaining agreement on consultant establishments until there is agreement on the amount of work and responsibility the average consultant should take and on the amount of junior help he should have. Consultant establishments must be based on the unit of a consultant with one houseman. (I include in the term "housemen" house officers and junior registrars, and in the term "registrars" registrars and senior registrars.) The establishment of registrars should be decided on a regional basis, and should depend on the number of consultant posts likely to be vacant in the region during the next five years. Allowance for wastage should not exceed 10% over three years for senior registrars, and 10% over two years for registrars. In non-teaching, but not in teaching, hospitals a consultant with a registrar would be able to manage a few additional beds.

Such a scheme would ensure proper distribution of consultants, and would give scope to the large number of trained men now out of work or labouring under the threat of dismissal.

Εἶδον.

"SUFFOCATION" IN INFANCY

SIR,—With the report and the leading article in your issue last week, the "suffocated" infant is in the medical news again and one's years-old doubts and queries about it come out for spring-cleaning. Bacteriology and histology may be completely unconvincing as to the cause of death. Can spasmophilia, due to altered biochemistry, play the trigger part in some cases?

Dr. F. B. Smith found palpably soft skull-bones in about one-third of his series. The pædiatricians will presumably agree that this proportion is far higher than that found in living infants of up to six months old, even if palpable denting is ever "normal" at this age—which I doubt. These infants are not seen by the pædiatricians. They go straight from their—usually humble—cots or prams to the mortuary. But the degree of craniotabes can be an eye-opener to hospital residents invited thither; either they have never seen it as students, or never such a degree of it.

What is the present consensus of pædiatric opinion on the significance of craniotabes at this age? (I realise that biochemical analysis in infants necessitates jugular, scalp-vein, or anterior-fontanelle puncture, and that X rays are unhelpful in the first year.) A few years ago, I was told that the general opinion in Scotland was judged to be that craniotabes was a sign of rickets; but a few weeks ago a consultant pædiatrician said that he would not treat it so, without other evidence in support, and, further, that he was seeing very little rickets at his clinics.

Another point: if craniotabes is acceptable as evidence of rickets, can the biochemical upset of rickets (and so the risk of laryngospasm) be present without palpable skull softening? If evidence is present of natural disease, capable of causing sudden or rapid death (and the books say that laryngospasm can kill rapidly), then most convincing evidence would be needed to support an opinion that death was unnatural. I can recall carrying a coroner with me in recording a natural death in an infant found with a pillow over its face.

Mark you, Sir, I have found craniotabes in an infant dying after a short illness in hospital, and then even more convincing meningococci in an early exudate on the brain within.

Department of Pathology,
General Hospital, West Hartlepool.

R. T. COOKE.

DIPHTHERIA IMMUNISATION

SIR,—There are just two points in Miss Barr's letter last week which require comment.

Miss Barr fears that, with the decline in the incidence of diphtheria infection, the Schick standard may prove inadequate to guarantee protection against the disease. I can only say that for many of the years during which my faith in the post-Schick negative result has been built up, adventitious stimuli, due to contact with infection, have been almost lacking. My opinion was not lightly formed, and it has been tested repeatedly by contact of my subjects with all grades of diphtheria infection. Such cases of the disease as have occurred in my previously post-Schick negative children have nearly always been mild and non-paralytic. Thus I do not share Miss Barr's apprehension on this point.

I should like to make it clear that when I referred to the consideration of single-injection prophylaxis I meant exactly what I said. In the past, one-shot immunisation had no more bitter opponent than myself, as manufacturers of such preparations may recollect. With the advent of ever-improving prophylactics, I certainly do not despair of the elaboration of a single-injection method which will control diphtheria adequately. I welcome the opportunity of boldly making a prophecy that this will happen.

Insistence on the necessity for an *orthodox* secondary response may well be a definite bar (sorry—no pun!) to progress. There is more in this remark than meets the eye, but I am working at the problem at the present time, and can only say that my results, so far, are more than encouraging.

Public Health Laboratory Service,
134, Denmark Hill, London, S.E.5.

GUY BOUSFIELD.

PERMANENT WAVING AT HOME

SIR,—It is now widely recognised that the home permanent-waving outfits which are on sale throughout the country depend for their action on ammonium thioglycollate, which is applied for a variable time and then neutralised by the application of potassium bromate.

The bromate is normally supplied in powder form which the user makes up into the neutralising solution by mixing with water. The resulting solution is colourless, odourless, and almost tasteless; and it is, therefore, possible that in spite of warnings issued by the manufacturers someone may drink it. Accordingly, it may be useful to note the instructions which have been issued in the United States for treatment of these cases:

> If the neutraliser has been swallowed, an emetic should be given: the stomach may be washed out. One level teaspoonful of sodium thiosulphate should be given after the patient has been sick. Demulcent drinks, such as milk and thin gruel, may then be taken. If shock is a feature, treat the patient for shock but avoid central nervous stimulants. Pain may be relieved with morphine. Intravenous therapy with sodium thiosulphate has been employed, either by the injection of 10–50 ml. of a 10% solution or by an intravenous drip using 100–500 ml. of a 1% solution.

R. M. B. MACKENNA.

London, W.1.

---

[1] *Times*, Dec. 31, p. 5.

University of Edinburgh

The Cameron prize for 1950 has been awarded to Dr. R. A. Peters, F.R.S., Whitley professor of biochemistry, Oxford, in recognition of his discovery of BAL (dimercaprol) and its application in practical therapeutics.

Harveian Society of London

Sir Henry Cohen will deliver the Harveian lecture at 26, Portland Place, London, W.1, on Wednesday, March 22, at 8.45 P.M. He will speak on Harvey and the Scientific Method.

Pharmaceutical Society of Great Britain

On Thursday, March 9, at 7.30 P.M., at 17, Bloomsbury Square, London, W.C.1, Mr. J. O. Irwin, D.SC., a member of the statistical research unit of the Medical Research Council, will speak on Statistics and Biological Assay.

Society of Chemical Industry

At a meeting of the microbiological panel to be held on Wednesday, March 8, at 6.15 P.M. at 11, Chandos Street, London, W.1. Dr. G. Pontecorvo will read a paper on the Impact of Genetics on Microbiology.

Royal Microscopical Society

On Wednesday, March 15, at 5.30 P.M., at B.M.A. House, Tavistock Square, London, W.C.1, Mr. G. H. Bourne, D.SC., will speak on Golgi Apparatus and Mitochondria and their Significance in Cellular Physiology.

Chadwick Public Lecture

On Tuesday, March 14, at 2.30 P.M., at Westminster Medical School, Horseferry Road, London, S.W.1, Dr. C. A. Boucher will speak on the Maintenance of Health by the Prevention of Accidents in the Home. At 2.15 P.M. the Chadwick prize of £100 and a medal is to be presented to Brigadier A. E. Richmond, M.R.C.S.

Rumania Withdraws from W.H.O.

Like the U.S.S.R., Byelorussia, the Ukraine, and Bulgaria, Rumania has withdrawn from the World Health Organisation. Announcing his country's withdrawal, the Rumanian minister of health alleges that W.H.O. has " been transformed into a bureaucratic institution which does not correspond to the tasks assigned it by its constitution." The decision of the five governments to discontinue participation will be submitted to the third World Health Assembly, which is to open at Geneva on May 8.

Liverpool Regional Hospital Board

At a meeting on Feb. 2, this board decided that for a trial period of twelve months the works and buildings committee should be authorised to delegate to hospital management committees the execution of individual capital works estimated to cost not more than £1000, in appropriate cases recommended by the board's officers.

Belmont Road Hospital, Liverpool, has been renamed Newsham General Hospital, and the Widnes Isolation Hospital has been renamed Widnes Convalescent Hospital.

Remuneration of Medical Civil Servants

As we announced a fortnight ago (*Lancet*, Feb. 18, p. 333,) the Treasury has rejected a claim by the Civil Service Medical Officers' Joint Committee for an immediate increase in salaries. The Treasury's letter of refusal states: "We intend, of course, in the case of medical officers employed on rates of salary above £1400 a year, to apply increases proportionate to those recommended by the Chorley Committee for the Administrative Class, such increases to take effect on an equal footing with the other improvements recommended by the Committee, and similar arrangements for postponement and title to superannuation will be made."

In his reply to the Treasury, Mr. Stanley Mayne, secretary of the joint committee, remarks that the committee's concern is twofold: (1) that the Treasury's letter makes no reference to the Spens reports, which, the committee holds, should be applied to medical officers in the Civil Service; and (2) that continued refusal to increase salaries will speed " the denigration of the medical Civil Service," which already has less than its full complement.

The joint committee was meeting Treasury officials last Wednesday.

National Association for Maternity and Child Welfare

Princess Elizabeth, president of the association, will open the annual conference on June 28, at Friends House, Euston Road, London, N.W.1. The conference will continue on June 29 and 30, and the general theme will be the Child and its Environment. Further information may be had from the secretary of the association, 5, Tavistock Place, London, W.C.1.

World Federation for Mental Health

The federation's executive board last week concluded a four-day meeting in London. At the end of the meeting Prof. H. C. Rumke (Holland), the president, told representatives of the press that the new movement for mental health was characterised by close integration between psychologists and psychiatrists; and the members of the team included sociologists, ecologists, anthropologists, philosophers, clergymen, and educationists. Dr. J. R. Rees, director and ex-president of the federation, reported that the membership included 62 societies from 33 countries; and associations in Eire, the Phillipines, and Iceland were expected to join soon. The annual meeting is to be held in Paris at the end of August.

French Government Exchange Scholarships

The Medical Research Council invite applications from British workers in medical science, excluding clinical medicine, for two scholarships tenable at research institutions in France during 1950–51. The scheme, which is part of a reciprocal arrangement with the Centre National de la Recherche Scientifique, is intended for young graduates in medicine or science who have already had some experience in a branch of medical science. Candidates must be of British nationality and have at least a working knowledge of French. The stipend will ordinarily be within the range of 30,000–60,000 francs a month, and married men will receive a supplementary allowance. Forms of application may be had from the secretary of the council, 38, Old Queen Street, London, S.W.1, to whom applications must be sent by March 31.

War Memorial for Nurses

Lord Moran is to broadcast at 8.45 P.M. on Sunday, March 12, in the Week's Good Cause in aid of the British Commonwealth and Empire Nurses War Memorial Fund, of which he is chairman of appeals. The fund, which was launched in 1946, now stands at over £71,000. It is hoped to reach £250,000 to form a fund to establish postgraduate travelling scholarships for nurses. The furnishing of a war memorial chapel in Westminster Abbey, the second object of the fund, has been already provided by the gifts of the nursing profession. At least £16,000 is needed to found a scholarship of not less than £350 per annum, although some donors, including the Royal College of Physicians, are giving 7-year scholarships under deed of covenant. An interim award of scholarships given outright in this way is being made this year, and candidates are being selected from the United Kingdom, Canada, Pakistan, Ceylon, Hong-Kong and Singapore, and Malaya. Gifts to the fund can be sent to Lord Moran, Appeals Office, 12, Whitehall, S.W.1.

Scottish Health Services Council

The following doctors have been appointed or reappointed to the Scottish Health Services Council and the standing advisory committees in place of those who retired on Dec. 31, 1949. Reappointments are indicated with an asterisk.

Scottish Health Services Council: Dr. R. W. B. Ellis, professor of child-life and health, University of Edinburgh; Mr. W. W. Galbraith, visitor, Royal Faculty of Physicians and Surgeons of Glasgow; Dr. I. D. Grant, chairman of Scottish committee of the British Med [illegible] . M. McAlister, medical superintendent, [illegible] W. R. Snodgrass, president of the Royal [illegible] and Surgeons of Glasgow, *Dr. David [illegible] ry, Pharmaceutical Society in Scotland; * [illegible] ast president, Royal College of Physicians, Edinburgh.

Medical advi [illegible] Cuthbertson, director, Rowett Resear [illegible]

Nursing and [illegible] *Dr. W. L. Burgess, M.O.H. Dundee.

P [illegible] M. Macleod, Inverness.

R [illegible] *committee:* *Dr. R. Ball [illegible]

L [illegible] *Dr. Kate Harrower, Glasgow.

Health-centres advisory committee: Dr. A. C. Blair, Kilsyth.

Highlands and Islands advisory committee: *Dr. A. J. Macleod, Lochmaddy, North Uist.

Notes and News

APPROVAL OF HOSPITAL MANAGEMENT COMMITTEES' ESTIMATES

THE Ministry of Health states that "in the light of the experience of the past twelve months it is apparent that no effective purpose is served by reserving to the Minister the formal approval of the estimates of individual Management Committees. It has therefore been decided to delegate this duty to Regional Hospital Boards subject only to the prior approval by the Minister of the total estimates for all the Committees in each Regional area." The revised procedure will operate for the year 1950–51 onwards, including revised estimates where necessary.

U.S.A. AND FOREIGN MEDICAL SCHOOLS

THE American Medical Association's council on medical education and hospitals, and the executive council of the Association of American Medical Colleges, report that they "are of the opinion that medical institutions and medical organizations in the United States would be justified in considering current and past graduates of the following foreign medical schools on the same basis that they consider graduates of approved medical schools in the United States":

Denmark.—University of Copenhagen.

Finland.—University of Helsinki; Turku University.

Netherlands.—University of Amsterdam; Royal University of Groningen; Royal University of Leiden; Royal University of Utrecht.

Norway.—University of Oslo.

Sweden.—Royal Charles University, Lund; Charles Medico-Surgical Institute, Stockholm; Royal University of Uppsala.

United Kingdo[illegible] Birmingham, Bristol, Cambridge, [illegible] ds, Liverpool, London, Manchest[illegible] and Wales; Queen's University, Belfast.

This list, to which additions will be made as further information becomes available, appears in the *Journal of the American Medical Association* of Feb. 25.

ARMY HEALTH FILMS

TWO additions to the War Office series of films on health education for the soldier have recently been produced for the Army Kinema Corporation.

Personal Hygiene (28 min., black-and-white) is designed, with commentary and animated diagram, to tell the soldier almost all he needs to know about his body. Kaleidoscopic snapshots of everyday physiology are humorously, simply, and attractively explained. Reasoned emphasis is laid on the value of fresh air, exercise, sensible food, and regular bowel habits in the "daily maintenance" of the body ("its your *own* property") to make each day feel manifestly worth living. Respiration, blood circulation, peristalsis, food hygiene, body odour, barrack-room ventilation, slumberwear, and droplet infection are among the topics described in some detail. Photography is very good and the camp settings realistic.

Health in Our Time (33 min., black-and-white) is a two-piece film. The first half, enriched by the pursuasive voice of the Radio Doctor, describes and illustrates civilian public-health activities. An account of the importance of proper water-supply, sewage disposal, and street cleansing (public services aptly referred to as "organised common sense") is followed by details of the measures taken at airports and seaports against the importation of infectious disease and bad food. Certain unhygienic sins of barmen and waitresses, grocers, gobblers, and gamblers are memorably photographed and convincingly deplored by Dr. Hill. Group radiography, diphtheria immunisation, and new houses are given their due place in the maintenance of health. This half of the film makes good showing to any adult audience, civilian or military. The second half, with comments to the soldier voiced by an Army medical officer, illustrates important points of military hygiene in temperate and tropical climates. Among the subjects portrayed are the preparation and use of vaccines, health education at the Army School of Hygiene, design of military uniforms for special purposes, and assessing the soldier for the job to which he is best suited. A moving articulated skeleton does "P.T." with the squad to demonstrate the purpose behind each exercise. Throughout this half of the film, the accent is on the importance of each and every soldiers' health contribution to the military efficiency and success of an army.

Copies of both films (16 mm.) may be hired from the Army Kinema Corporation, 36, Dover Street, London, W.1.

NEIGHBOUR'S FARE

MANY of us are the sons and grandsons of doctors, but few can, have started so early in the calling of medicine as Dr. Donald McI. Johnson: at eighteen months, he tells us in his autobiography,[1] he went out on his father's rounds. An only child with a lovable and dominating father and an anxious depressed mother, he was, as it were, trapped into the service of his fellow men. Small wonder then that this book is a record—a very moving record—of his struggles to find himself while doing justice to others. His voice is that of the general practitioner of today; and though some of the dissatisfaction it expresses may be discounted as personal, much of it cannot, for the author is capable of being objective, and has understanding of his own and his patients' limitations and frustrations.

It would be wrong, however, to consider this book solely in relation to the practice of medicine. It is a personal story honestly and lucidly told. Childhood, unhappy school-days, Cambridge, London hospitals, and general practice in a London suburb—all these are passionately remembered and soberly described. The chapter on his excursion into politics at a by-election is funny, true, and simply set down. The illustrations include some lovely photographs of the Arctic seas and mountains.

THE INDEX-CATALOGUE

SOME weeks ago we referred[2] to the rumoured discontinuance of the *Index-Catalogue* of the U.S. Army Medical Library. Major-General R. W. Bliss, the surgeon-general, has now confirmed that publication is to cease with the completion of volume eleven of the fourth series. Thereafter the Army medical library plans to publish a volume or volumes to complete the record of its monographic holdings up to the mid-century mark; and beyond that to publish selectively the most useful portion of the subject-references (numbering over 1,750,000) that have not yet been recorded. Provision for a continuing record of the library's monographic holdings has been assured in the form of an annual supplement to the *Library of Congress Catalog of Printed Cards*. At the same time the library's *Current List of Medical Literature* will be augmented and improved; an author-index will be added, a standard list of journals to be covered regularly introduced, classification by broad journal groupings abandoned, and a cumulative subject-index provided; the format and frequency of publication may be altered.

University of Oxford

An election of one member of the board of the faculty of medicine in place of Mr. E. A. Crook, who is eligible for re-election, will be held on May 31. Nominations should reach the secretary of faculties at the university registry before 10 A.M. on May 3.

University of London

Dr. D. D. Reid has been appointed to the readership in epidemiology and vital statistics at the London School of Hygiene and Tropical Medicine.

Dr. Reid, who is 35 years of age, was educated at the Royal Academy, Inverness, and the University of Aberdeen, where he graduated M.B. in 1937. After [illegible] the Royal [illegible] in London, Northern I[illegible] Command. he joined t[illegible] esearch staff of the *Directorate*-Later he w[illegible] General of [illegible] is the author of three chapters in *Psychologic*[illegible] *Personnel in the R.A.F.* and of papers on r[illegible] *British Journal of Social Medicine*. In 1946 h[illegible] with commendation and appointed lecturer i[illegible] he London School of Hygiene and Tropical [illegible] eceived the PH.D. Lond., and while holding a [illegible] ellowship he was visiting associate professor [illegible] School of Public Health of the University of California.

Dr. A. E. W. Miles, F.D.S. R.C.S., has been appointed to the chair of dental pathology at the London Hospital Medical College.

The title of professor emeritus of chemistry has been conferred on Mr. C. S. Gibson, F.R.S., on his retirement from the chair of chemistry at Guy's Hospital Medical School, which he has held since 1921. The title of professor emeritus of physiology has been conferred on Dr. Hamilton Hartridge, F.R.S., who held the chair of physiology at St. Bartholomew's Hospital Medical College from 1927 to 1947.

---

[1] A Doctor Regrets. London: Christopher Johnson. 1949. Pp. 242. 12s. 6d.

[2] *Lancet*, Jan. 28, p. 172.

Usually the patient has no difficulty in swallowing the tube. Having swallowed it, he is taught how to regulate the rate of the drip and to estimate the correct rate. He is allowed to discontinue the drip to wash or visit the toilet.

While on the drip he has a routine gastric diet, as follows:

6.30 A.M.	Cup of weak milky tea.
8.15 A.M.	Breakfast.
10.15 A.M.	Cup of hot milk.
12.15 P.M.	Lunch.
2.15 P.M.	Cup of weak milky tea.
4.15 P.M.	Tea.
6.15 P.M.	Supper.
9.00 P.M.	Hot milk drink.

This diet excludes gross roughage, chemical irritants, and fried foods.

During meals the patient is allowed to discontinue the drip and remove the Ryle's tube. After the meal he washes, cleans, and swallows his tube and starts the drip again. If, as occasionally happens, the tube becomes blocked, the patient withdraws it, syringes it clean with water, and immediately swallows it again.

The more seriously ill patients—for example, those who have had a recent hæmorrhage—are confined strictly to bed on a milk drip without additional nourishment.

The patients on a milk drip are given gr. 1 of phenobarbitone twice daily, to ensure mental rest; those on the magnesium-bicarbonate drip also receive 15 minims of tincture of opium to combat the tendency to diarrhœa. All are given 50 mg. of ascorbic acid daily, and if anæmia is present ferrous sulphate is given.

After the first week in bed patients who are fit enough take part four times weekly in a ward class of physical exercises similar to those recommended by Dr. Geoffrey Evans (1945). For these the patient lies outside the bedclothes with his drip still running.

The drip is continued for three weeks, which is the maximum period which most patients can comfortably tolerate. Thereafter the patient spends a further week in bed and then, if symptom-free, he is allowed up gradually.

Where there is reason to expect relapse, the patient is advised to set up a drip at home, for use during the night, or continuously over a week-end, or for longer periods, if there is any recurrence of pain. Many man-hours in industry could be saved in this way by the early prevention of true relapses. Many hospital beds could also be saved if patients with a peptic ulcer who have suitable home conditions were treated at home by the continuous-drip method, using magnesium bicarbonate solution when enough milk is not obtainable.

In my experience the drip is most likely to benefit the "low grumbling" type of ulcer case. In chronic cases it is usually disappointing.

The Drip and Hæmatemesis

Opinion on the best treatment of recent hæmatemesis and melæna now generally supports Meulengracht in his advocacy of immediate liberal feeding; but some acutely ill patients are unwilling or unable to take so full a diet. A constant milk drip fulfils the principles of Meulengracht by providing adequate fluid and calories. If there has been much vomiting, salt can be added to the milk in the reservoir; extra vitamin C can also be added. If the patient wishes to take anything by mouth, sips of glucose saline are allowed; five to seven days after the bleeding has ceased, semi-solid milk feeds are given in addition to the drip; and three weeks after bleeding has ceased nearly all patients should be on full convalescent gastric diet.

In these cases the drip affords the stomach maximal rest with minimal distention.

Rate of Flow

During the 24 hours the drip is out of action for about 3 hours, on the average, owing to interruption by meals, toilet, and cleansing of the tube. Occasionally, while asleep, the patient stops the flow by lying on the tube or clenching his teeth on it; and it is the duty of the ward staff to rectify such stoppages without disturbing the patient unduly.

The aim is to give, in the 24 hours, 100 oz. of milk, citrated by the addition of gr. 40 of sodium citrate to the pint, or 80 oz. of magnesium bicarbonate solution (Dinneford's fluid magnesia) diluted 1 in 3 with water. The milk is allowed to flow at 50 drops per minute, which will supply 105 oz. in 21 hours; for the magnesium bicarbonate solution the rate of flow is 40 drops per minute, giving 84 oz. in 21 hours.

RESULTS

With one exception (a serving soldier) every patient in this series is a man receiving a disablement pension, which means that the ulcer is either due to service in the Forces or was aggravated by such service. Of the 35 patients, 5 were admitted to hospital after either a hæmatemesis or the start of a severe melæna.

The most notable feature was the almost instantaneous relief of abdominal pain. In every case, no matter how severe the pain, relief was obtained within 36 hours, of the start of the drip. In no case were ancillary drugs required. This relief was equally remarkable with both milk and the magnesium bicarbonate solution.

During the three weeks on the drip 4 patients, all over-weight for their size, lost weight; in 2 the weight remained stationary; and the remaining 29 gained an average of just over $5\frac{1}{2}$ lb., the maximum gain being 15 lb.

The drip was a great emotional stimulant, especially in patients who had had medical treatment elsewhere. No patient had previously been treated by the drip method; and any lack of confidence was soon rectified by the rapid relief of pain with the resulting sense of well-being, and also by the discovery that having a tube in situ all day was not so unpleasant as had been anticipated. This more cheerful outlook, coupled with the improved general condition, was an asset in preparing patients for surgical treatment.

Of the 35 patients, 33 were examined radiologically before the drip was begun. In 29 an ulcer was demonstrated; in the remaining 6 the diagnosis was made on the history and clinical findings.

Of the 29 radiologically positive cases, 19 showed no radiographic evidence of an ulcer one to sixteen weeks after the drip had ended. One of this group was not symptom-free, and in view of his age and his five-year history, surgical intervention was advised; this he refused.

A further 5 cases, examined up to two weeks after the drip had ended, showed either a small residual ulcer or an ulcer in which well-marked healing had taken place.

The remaining 7 cases at periods of one to four weeks after the drip had ended still had an active ulcer, judged either clinically or radiologically. In most of these surgery was advised and all but 1 of the cases operated on were found to have a large chronic ulcer with multiple adhesions, the 1 exception having a gastric carcinoma.

The only clinical disadvantage was the tendency to diarrhœa with the magnesium bicarbonate drip. In only 1 case was this so severe that the solution had to be replaced by milk: all the remaining patients settled down after the first two or three days to an average of two bowel actions daily, provided 15 minims of tincture of opium was added to the reservoir twice a day.

BIOCHEMICAL INVESTIGATIONS

In order to make a satisfactory comparison between the value of milk and magnesium bicarbonate solution as neutralising agents, samples of the gastric contents were withdrawn from patients on the drip for estimations of free acid and pH. The samples were withdrawn at two-hourly intervals between 10 A.M. one day and 8 A.M.

Visit of French Medical Specialists

Ten French doctors are visiting this country at the invitation of the British Council to study recent developments in British medicine. The Royal College of Physicians, the Royal College of Surgeons, and the Royal Society of Medicine are arranging functions in honour of their colleagues.

Sir Cecil Wakeley, P.R.C.S., has been appointed chevalier of the Legion of Honour of the French Republic in recognition of services rendered during the war.

The latest annual report of the Pest Infestation Research Board has been published for the Department of Scientific and Industrial Research by H.M. Stationery Office. The report is entitled *Pest Infestation Research, 1948* (pp. 32. 1*s.*).

CORRIGENDA: *The Iron and Steel Industry.*—In this article (Feb. 4) by Dr. Catherine Swanston, in the table of deaths from silicosis on p. 195, the last entry under "Industry" should read "All others" (*not* "All other metal-workers").

Small-pool Plasma.—In our account last week of the discussion on hepatitis by the Royal Society of Medicine Dr. W. d'A. Maycock was reported (p. 356) as having said that enough small-pool plasma is now being produced to meet the needs of hospitals. Actually, Dr. Maycock expressed the hope that enough to meet these needs will be produced in the next twelve months.

Appointments

ALMOND, H. G. A., M.B., M.CH. (ORTH.) Lpool, F.R.C.S.: orthopædic surgeon, orthopædic clinics of school health service, Liverpool.

AYOUB, J. E. M., B.A., B.M. Oxfd, F.R.C.S.: part-time consultant surgeon, Moorfields Westminster and Central Eye Hospital (Moorfields branch).

BORTHWICK, J. B., M.B.E., M.D. Edin., F.R.C.P.E.: asst physician, Scottish Borders hospitals group.

CAMPBELL, J. A., M.A., M.B. Camb., M.R.C.P., D.T.M. & H.: consultant physician, Norfolk and Norwich area.

CUNNINGHAM, R. C., M.B. Glasg., D.P.H., D.P.M.: senior M.O., mental-health section, Essex.

DAVIES, I. J., M.D., B.SC. Wales, D.P.M.: consultant psychiatrist and medical superintendent, St. Audrey's Hospital, Melton, Cambs.

DOWNES, C. E. P., M.R.C.P.: consultant chest physician, Huntingdon and Isle of Ely area.

FINE, WILFRED, M.D. Lond., M.R.C.P.: consultant non-resident deputy physician-superintendent, Newsham General Hospital (previously Belmont Road Hospital), Liverpool.

FRANK, J. R., M.B. Edin., F.R.C.S.E.: asst. surgeon, Scottish Borders hospitals group.

GREEN, DORA, B.SC. Lond., M.R.C.S., D.C.H.: asst. M.O.H. and asst. schools M.O., Luton.

HAY, C. P., M.D. Edin., M.R.C.P.E., D.P.H.: consultant chest physician, West Suffolk area.

HINGSTON, ETHELINE, B.A., M.B., Dubl., D.C.H.: asst. M.O., combined health and schools service, Leeds.

HOWARD, STANLEY, M.B. Lpool.: senior asst. M.O.H. for duties in connection with care and aftercare scheme, Bradford.

HUDSON, J. R., M.B. Lond., F.R.C.S., D.O.M.S.: assistant in ophthalmic outpatient department, Middlesex Hospital, London.

MINTO, W. H. P., M.B. Aberd., D.P.H.: district M.O.H., and asst. county M.O., Brixworth, Northants.

MORRISON, J. B., M.D., B.SC. Glasg.: medical superintendent, Abergele Sanatorium.

MOSELEY, J. H., M.A., M.B. Camb., M.R.C.P.: consultant pædiatrician, Portsmouth and Isle of Wight.

O'MALLEY, A. G., M.B., M.CH. (ORTH.) Lpool, F.R.C.S.: consultant orthopædic surgeon, St. Helens Hospital.

O'MALLEY, C. J. S., C.B.E., M.B. Lond.: director of rehabilitation, Garston Manor.

PEARCE, R. D., M.R.C.S.: asst. county M.O.H., for duties in Grays, Hornchurch, and Brentwood areas, Essex.

RICHARDSON, H. J., L.R.C.P.E., D.A.: consultant anæsthetist, Peterborough area.

RIVLIN, LILY, M.R.C.S.: asst. M.O., county health department, Middlesex.

ROE, P. W., B.A., B.M. Oxfd: physician, Watford Chest Clinic and Shrodells and Harefield Hospitals, Herts.

ROGERS, W. F., B.A., M.D. Dubl.: medical registrar, White Lodge Hospital, Newmarket.

RYAN, J. J., M.B., B.SC. N.U.I., D.P.H., D.P.M.: consultant psychiatrist and deputy medical superintendent, Little Plumstead Colony.

STEPHEN, MARGARET, M.B. Glasg., D.P.H.: asst. M.O., area no. 8, Middlesex.

SWERDLOW, MARK, M.B., B.SC., Manc., D.A.: anæsthetist, hospitals in St. Helens and Warrington areas.

YOUNG, I. M., M.B. Glasg.: consultant chest physician, Great Yarmouth and Lowestoft area.

St. Thomas's Hospital, London:

CHURCHILL-DAVIDSON, H. C., M.A., M.B. Camb., D.A.: senior registrar, anæsthetics department.

COLE, J. G. L., M.B. Birm.: senior registrar, X-ray diagnostic department.

PIERCE, J. W., M.D. Lond., M.R.C.P., D.M.R.D., radiologist, X-ray diagnostic department.

SUTCLIFFE, JOHN, M.B. Camb., M.R.C.P.: senior registrar, X-ray diagnostic department.

Diary of the Week

MARCH 5 TO 11

Monday, 6th

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Mr. A. Dickson Wright: Surgical Aspects of Hyperpiesia. (Last Lettsomian lecture.)

NATIONAL HOSPITAL, Queen Square, W.C.1
5 P.M. Prof. J. A. Barré (Strasbourg): Formes cliniques actuelles des troubles extenso-progressifs d'origine traumatique et de nature réflexe.

Tuesday, 7th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. R. S. Murley: Postoperative Venous Thrombosis and Embolism. (Hunterian lecture.)

INSTITUTE OF DERMATOLOGY, Lisle Street, W.C.2
5 P.M. Dr. F. R. Bettley: Seborrhœic Dermatitis.

Wednesday, 8th

ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. Milroy Paul: Blood and Lymph Pathways in the Spermatic Cord. (Hunterian lecture.)

UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Dr. S. Galbraith: Evolution of the Ophthalmoscope.

Thursday, 9th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. J. B. Oldham: Renal Denervation. (Hunterian lecture.)

INSTITUTE OF DERMATOLOGY
5 P.M. Dr. L. Forman: Drug Eruptions.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Dr. Desmond Curran: Psychiatry lecture-demonstration.

ADLERIAN SOCIETY OF GREAT BRITAIN
8 P.M. *Medical Section* (11, Chandos Street, W.1). Dr. Ethel Dukes: Psychological Aspects of Marriage Guidance.

Friday, 10th

NATIONAL HOSPITAL, Queen Square, W.C.1
5 P.M. Prof. A. G. Weiss (Strasbourg): Operative Treatment of Hypertension.

MAIDA VALE HOSPITAL MEDICAL SCHOOL, W.9
5 P.M. Dr. Helen Dimsdale: Neurological demonstration.

WEST KE [illegible] OCIETY
8.30 P. [illegible] .) Dr. Robert Forbes: Legal [illegible]

Saturday, 11th

SOUTH EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY
10.30 A.M. (Guy's Hospital, S.E.1.) Dr. E. R. Boland: Minimal Tuberculous Lesions and their Treatment.

Births, Marriages, and Deaths

BIRTHS

BARLOW.—On Feb. 16, the wife of Dr. T. G. Barlow—a son.

BENSON.—On Feb. 12, in London, the wife of Dr. Robert Benson—a son.

COPEMAN.—On Feb. 23, the wife of Dr. H. Copeman—a daughter.

COX.—On Feb. 22, in London, the wife of Dr. A. G. Charlton Cox—a daughter.

COXON.—On Jan. 17, at Oxford, to Dr. Mary Coxon, wife of Mr. R. V. Coxon—a son.

DANBY.—On Feb. 23, the wife of Dr. Anthony Danby—a son.

FITCH.—On Feb. 23, at Bishopsbourne, the wife of Lieut.-Colonel Keith Fitch, O.B.E., F.R.C.S.—a daughter.

GIFFORD.—On Feb. 19, the wife of Dr. L. A. Gifford—a son.

HARVEY.—On Feb. 18, in London, the wife of Dr. R. M. Harvey—a daughter.

HAWKINS.—On Feb. 18, the wife of Dr. L. A. Hawkins—a son.

H[illegible]—On Feb. 20, at Dorchester, Dorset, the wife of [illegible]—a daughter.

[illegible] Cold Ash, Newbury, the wife of Captain A. Paton, R.A.M.C.—a son.

ROBINSON.—On Feb. 18, the wife of Dr. G. A. Robinson—a daughter.

TEMPLE.—On Feb. 19, in London, the wife of Mr. J. L. Temple, F.R.C.S.—a son.

MARRIAGES

HOLROYD—TWOMEY.—On Feb. 4, in London, F. Lister Holroyd, major, R.A.M.C., to Kathleen Twomey.

SPRUELL—BROWN.—On Feb. 18, at Sale, Cheshire, George Kerr Spruell, M.B., to Joan Bruce Brown.

DEATHS

BRISTOW.—On Feb. 21, at Bournemouth, William Moss Bristow, L.R.C.P.E.

FISON.—On Feb. 25, at Salisbury, Edmund Towers Fison, O.B.E., B.A., M.D. Camb., F.R.C.S.E., D.P.H., aged 80.

FLEWITT.—On Feb. 26, in London, Charles York Flewitt, M.B. Birm., aged 73.

HARVEY.—On Feb. 23, William John Saundry Harvey, D.S.O., M.R.C.S., lieut-colonel, R.A.M.C. retd, aged 79.

LASLETT.—On Feb. 20, at Farnworth, Lancs, Thomas George Laslett, M.R.C.S., aged 90.

SHELDON.—On Feb. 18, Harold Sheldon, M.D. Manc.

THOMAS.—On Feb. 24, Hugh Arwel Thomas, M.B. Lpool, M.SC. Wales, D.P.H.

WHITE.—On Feb. 21, at Saltcoats, Ayrshire, John Allan White, M.B. Glasg.

WHITNALL.—On Feb. 19, Samuel Ernest Whitnall, M.A., D.M. Oxfd, F.R.S. Canada.

Usually the patient has no difficulty in swallowing the tube. Having swallowed it, he is taught how to regulate the rate of the drip and to estimate the correct rate. He is allowed to discontinue the drip to wash or visit the toilet.

While on the drip he has a routine gastric diet, as follows:

6.30 A.M.	Cup of weak milky tea.
8.15 A.M.	Breakfast.
10.15 A.M.	Cup of hot milk.
12.15 P.M.	Lunch.
2.15 P.M.	Cup of weak milky tea.
4.15 P.M.	Tea.
6.15 P.M.	Supper.
9.00 P.M.	Hot milk drink.

This diet excludes gross roughage, chemical irritants, and fried foods.

During meals the patient is allowed to discontinue the drip and remove the Ryle's tube. After the meal he washes, cleans, and swallows his tube and starts the drip again. If, as occasionally happens, the tube becomes blocked, the patient withdraws it, syringes it clean with water, and immediately swallows it again.

The more seriously ill patients—for example, those who have had a recent hæmorrhage—are confined strictly to bed on a milk drip without additional nourishment.

The patients on a milk drip are given gr. 1 of phenobarbitone twice daily, to ensure mental rest; those on the magnesium-bicarbonate drip also receive 15 minims of tincture of opium to combat the tendency to diarrhœa. All are given 50 mg. of ascorbic acid daily, and if anæmia is present ferrous sulphate is given.

After the first week in bed patients who are fit enough take part four times weekly in a ward class of physical exercises similar to those recommended by Dr. Geoffrey Evans (1945). For these the patient lies outside the bedclothes with his drip still running.

The drip is continued for three weeks, which is the maximum period which most patients can comfortably tolerate. Thereafter the patient spends a further week in bed and then, if symptom-free, he is allowed up gradually.

Where there is reason to expect relapse, the patient is advised to set up a drip at home, for use during the night, or continuously over a week-end, or for longer periods, if there is any recurrence of pain. Many man-hours in industry could be saved in this way by the early prevention of true relapses. Many hospital beds could also be saved if patients with a peptic ulcer who have suitable home conditions were treated at home by the continuous-drip method, using magnesium bicarbonate solution when enough milk is not obtainable.

In my experience the drip is most likely to benefit the "low grumbling" type of ulcer case. In chronic cases it is usually disappointing.

The Drip and Hæmatemesis

Opinion on the best treatment of recent hæmatemesis and melæna now generally supports Meulengracht in his advocacy of immediate liberal feeding; but some acutely ill patients are unwilling or unable to take so full a diet. A constant milk drip fulfils the principles of Meulengracht by providing adequate fluid and calories. If there has been much vomiting, salt can be added to the milk in the reservoir; extra vitamin C can also be added. If the patient wishes to take anything by mouth, sips of glucose saline are allowed; five to seven days after the bleeding has ceased, semi-solid milk feeds are given in addition to the drip; and three weeks after bleeding has ceased nearly all patients should be on full convalescent gastric diet.

In these cases the drip affords the stomach maximal rest with minimal distention.

Rate of Flow

During the 24 hours the drip is out of action for about 3 hours, on the average, owing to interruption by meals, toilet, and cleansing of the tube. Occasionally, while asleep, the patient stops the flow by lying on the tube or clenching his teeth on it; and it is the duty of the ward staff to rectify such stoppages without disturbing the patient unduly.

The aim is to give, in the 24 hours, 100 oz. of milk, citrated by the addition of gr. 40 of sodium citrate to the pint, or 80 oz. of magnesium bicarbonate solution (Dinneford's fluid magnesia) diluted 1 in 3 with water. The milk is allowed to flow at 50 drops per minute, which will supply 105 oz. in 21 hours; for the magnesium bicarbonate solution the rate of flow is 40 drops per minute, giving 84 oz. in 21 hours.

RESULTS

With one exception (a serving soldier) every patient in this series is a man receiving a disablement pension, which means that the ulcer is either due to service in the Forces or was aggravated by such service. Of the 35 patients, 5 were admitted to hospital after either a hæmatemesis or the start of a severe melæna.

The most notable feature was the almost instantaneous relief of abdominal pain. In every case, no matter how severe the pain, relief was obtained within 36 hours, of the start of the drip. In no case were ancillary drugs required. This relief was equally remarkable with both milk and the magnesium bicarbonate solution.

During the three weeks on the drip 4 patients, all over-weight for their size, lost weight: in 2 the weight remained stationary; and the remaining 29 gained an average of just over 5½ lb., the maximum gain being 15 lb.

The drip was a great emotional stimulant, especially in patients who had had medical treatment elsewhere. No patient had previously been treated by the drip method; and any lack of confidence was soon rectified by the rapid relief of pain with the resulting sense of well-being, and also by the discovery that having a tube in situ all day was not so unpleasant as had been anticipated. This more cheerful outlook, coupled with the improved general condition, was an asset in preparing patients for surgical treatment.

Of the 35 patients, 33 were examined radiologically before the drip was begun. In 29 an ulcer was demonstrated; in the remaining 6 the diagnosis was made on the history and clinical findings.

Of the 29 radiologically positive cases, 19 showed no radiographic evidence of an ulcer one to sixteen weeks after the drip had ended. One of this group was not symptom-free, and in view of his age and his five-year history, surgical intervention was advised; this he refused.

A further 5 cases, examined up to two weeks after the drip had ended, showed either a small residual ulcer or an ulcer in which well-marked healing had taken place.

The remaining 7 cases at periods of one to four weeks after the drip had ended still had an active ulcer, judged either clinically or radiologically. In most of these surgery was advised and all but 1 of the cases operated on were found to have a large chronic ulcer with multiple adhesions, the 1 exception having a gastric carcinoma.

The only clinical disadvantage was the tendency to diarrhœa with the magnesium bicarbonate drip. In only 1 case was this so severe that the solution had to be replaced by milk: all the remaining patients settled down after the first two or three days to an average of two bowel actions daily, provided 15 minims of tincture of opium was added to the reservoir twice a day.

BIOCHEMICAL INVESTIGATIONS

In order to make a satisfactory comparison between the value of milk and magnesium bicarbonate solution as neutralising agents, samples of the gastric contents were withdrawn from patients on the drip for estimations of free acid and pH. The samples were withdrawn at two-hourly intervals between 10 A.M. one day and 8 A.M.

the next day, from consecutive patients until 50 groups of samples had been obtained in respect of both milk and bicarbonate solution. Some 600 samples of gastric contents were therefore obtained for each type of treatment. The patients were not selected, except that each had an ulcer which was held to require drip therapy. Whenever possible, a fractional test-meal was done before the drip was begun; but the selection of cases was not influenced by the result.

The patient was allowed nothing to eat or drink in the 90 minutes preceding the aspiration, with the exception of the 10 P.M. sample when the period was 60 minutes. Thus the aspirations could be regarded as carried out on an empty or resting stomach.

When the time for aspiration was reached, the Ryle's tube was disconnected from the drip system and swallowed another 4 inches, or more if necessary, so that it rested in the stomach. Then 30–40 c.cm. of air was blown through the tube to eject any drip solution remaining in it and to intermix the gastric contents. A sample of about 10 ml. of gastric contents was now withdrawn and saved; and if possible a further sample was withdrawn for the estimations. The patient then resumed his drip, withdrawing the Ryle's tube so that its tip rested in the œsophagus.

The samples were stored in a refrigerator until all twelve aspirations had been done. To determine whether this storage affected the findings, one set of samples was estimated immediately after withdrawal and again after 60 hours' refrigeration; no significant variation was found.

An attempt was made to obtain a representative sample of the whole gastric contents by blowing air down the Ryle's tube to aid mixing, and by discarding the first sample taken.

On being passed into the stomach, the Ryle's tube acts as a foreign body and therefore irritates and stimulates the gastric mucosa, with possibly a resulting outpouring of acid. This would not favour the results, which would thus tend to have a higher free-acid content.

Statistical Analysis of Findings

The aspirations covered a total of 101 24-hour periods. With 12 tests per 24-hour test period there should have been 1212 acidity and pH determinations; but on 10 occasions no sample was available and only 1202 tests were analysed.

For statistical analysis the results were placed into four groups, according to the composition of the drip: (1) citrated fresh milk containing gr. 40 of sodium citrate per pint; (2) Dinneford's fluid magnesia diluted 1 in 3; (3) citrated milk followed by Dinneford's fluid magnesia; and (4) Dinneford's fluid magnesia followed by citrated milk.

The conclusions drawn from the analysis are as follows. There is a good linear correlation between the pH value of the stomach contents and the logarithm of the stomach acidity. The experimental results are best represented by the equation: $\text{pH} = (3{\cdot}6 - 1{\cdot}3 \log_{10} F) \pm 0{\cdot}25$. There is no correlation between the mean stomach acidity over the 24-hour test period and the duration of the drip before testing. The use of a 1-in-3 solution of magnesium bicarbonate at a rate of flow of 80 oz. per 24 hours, followed by citrated milk at a rate of flow of 100 oz. per 24 hours, or vice versa, gives rise to lower stomach acidities than either of these agents used alone; considered as a whole, however, the differences are no greater than could be accounted for by normal variation, and the evidence is insufficient for the separation of the four groups into any order of merit.

CONCLUSIONS

The continuous intra-œsophageal drip is a satisfactory method for the medical treatment of acute and subacute peptic ulcer under present-day conditions, especially when there is considerable pain associated with gastric and pyloric spasm.

This form of treatment requires the least attention from the nursing staff and thus enables a small staff to care for more patients.

The constant drip keeps the gastric contents neutral throughout the 24 hours better than intermittent feeding methods, and affords the stomach maximal rest.

This method is suitable for the treatment of recent hæmatemesis, and where the general condition is poor or the patient needs "building up" before operation.

The best solution for the drip is fresh milk citrated with gr. 40 of sodium citrate to the pint, delivered at a rate of 100 oz. in 24 hours.

The next most satisfactory solution is magnesium bicarbonate in a 1-in-3 dilution of the *B.P.* solution, delivered at 80 oz. per 24 hours. This has the disadvantages of being laxative and not having the nutritive value of milk. Usually its laxative action can be effectively combated by adding 15 minims of tincture of opium to the drip reservoir twice daily.

There is no danger of alkalosis developing with either milk or the magnesium bicarbonate solution.

Patients have no difficulty in accommodating themselves to the constant drip, provided the Ryle's tube is swallowed by mouth, the end resting in the œsophagus just above the cardia.

I wish to thank the Director-General of the Ministry of Pensions Medical Services for permission to publish this paper, and Mr. L. J. Edwards, M.SC., F.R.I.C., of the Beecham Research Laboratories Ltd., for the statistical analysis.

PHÆOCHROMOCYTOMA OF THE ADRENAL

J. N. WALTON
M.B. Durh., M.R.C.P.
MEDICAL REGISTRAR, ROYAL VICTORIA INFIRMARY, NEWCASTLE UPON TYNE

PHÆOCHROMOCYTOMA or chromaffinoma is commonly considered a rare condition. Such tumours have been described arising from chromaffin tissue throughout the body, but it is when they arise from the medulla of the adrenal gland that the dramatic symptom-complex known as the adrenal sympathetic syndrome (Mac Keith 1944) is produced. Most of these tumours are pathologically benign, but the syndrome they produce is inevitably fatal unless the tumour is removed. Improved methods of diagnosis and treatment have developed from recent biochemical and physiological investigations.

The first reported case was probably that of Frankel (1886) who found bilateral adrenal tumours in a girl of 18 who for three years had had attacks of palpitations, headaches, and vomiting. In 1917 Volhard removed a kidney and adjacent tumour in 2 patients with hypertension and albuminuria, but the characteristic clinical picture of paroxysmal hypertension was first described by Labbé et al. in 1922. Mayo, in 1927, successfully extirpated a retroperitoneal tumour in a case showing the typical syndrome, but without recognising the exact nature of the neoplasm; however, in 1929 cure followed operation by Shipley in a case accurately diagnosed by Pincoffs. Chromaffinomata in other sites, occasionally multiple (Kipkie 1947), have been widely reported. The carotid body, sacrococcygeal region, retroperitoneal tissues, and intestinal wall have been implicated in addition to the adrenal.

In all, about 194 cases have been reported, of which less than a third have shown hormonal activity (Calkins and Howard 1947); the latter have all been found arising from the adrenal or from the retroperitoneal tissue nearer the midline (Mac Keith 1944). In one of the cases reported by Espersen and Dahl-Iversen (1946), the tumour appeared to arise from retroperitoneal tissue, but it was connected by a narrow pedicle to the left adrenal gland; and possibly many of the similar retroperitoneal tumours reported may have originated in this way. Eighteen bilateral adrenal tumours appear to have been reported, the last by Reid and Salm (1949).

That the condition is not so rare as was once thought is suggested by the number of cases recorded in the last few years (Roth and Kvale 1945, Espersen and Dahl-Iversen 1946, Washington et al. 1946, Blacklock et al. 1947, Brunschwig 1947, Goldenberg et al. 1947, Gutmann 1947, Mandl 1947, Schneider 1947, Spalding 1947, Alwall and Wulff 1948, Guarneri and Evans 1948, LaDue et al. 1948, Spear and Griswold 1948, Reid and Salm 1949). This increase is undoubtedly due to improved methods of diagnosis, but the difficulties which must still abound are well demonstrated in the review of Green (1946), who found that, of 51 cases, 37 had persistent chronic hypertension, sometimes with complete lack of fluctuation. Further, Smithwick, in a personal communication to Goldenberg et al. (1947) reported that in 1000 cases operated on for essential hypertension, the incidence of phæochromocytoma was 0·5%.

INCIDENCE

The disease occurs equally in the two sexes, and most often between the ages of 20 and 30 (Mac Keith 1944) or 25 and 45 (Biskind et al. 1941), though several cases have been reported in children (e.g., Holst 1938). Often a familial incidence has been noted (Hyman and Mencher 1943) and also an association with other endocrine disturbances, such as thyrotoxicosis, in the family (Hyman and Mencher 1943, Espersen and Dahl-Iversen 1946, Reid and Salm 1949). Mac Keith (1944) has noted an association with neurofibromatosis in some cases.

PATHOLOGY

The great majority of the tumours are benign, but up to 1944 there had been 15 clearly malignant cases recorded. Many of the malignant tumours are indistinguishable by their symptomatology from the simple ones, but for no apparent reason those which give rise to metastases do not produce the typical syndrome (Washington et al. 1946). The tumours have been shown to produce their effect by means of a pressor substance, akin to adrenaline, which is found in excess in the circulating blood. An increase of adrenaline in the peripheral blood during an attack of paroxysmal hypertension was first demonstrated by Beer et al. in 1937; and this was confirmed in 1939 by Strombeck and Hedberg, who found the blood-adrenaline content increased 30 times between attacks and 1000 times in an attack, though Volhard (1944) was unable to confirm these high figures. Assays of the adrenaline content of these tumours have given varying findings. Formerly adrenaline itself was regarded as the pressor agent responsible for the typical symptom-complex; but Holton (1949) suggests that noradrenaline, of which she found large quantities in three typical tumours, may be the causal agent.

CLINICAL PICTURE

The clinical picture falls into one of the following categories: (1) paroxysmal hypertension, (2) persistent hypertension, (3) malignancy, (4) Addison's disease due to compression of adrenal cortex, and (5) asymptomatic.

The asymptomatic group is of no clinical importance unless the tumour becomes large enough to encroach on important neighbouring structures. Cases belonging to the *third* and *fourth* categories are very rare; *it is in* fact questionable whether these tumours have ever been observed to give rise to Addison's disease. Of the 15 *malignant cases mentioned by* Mac Keith (1944), the majority were without metastases and had produced the well-recognised clinical picture of the first category —paroxysmal hypertension—and it was only at operation or even on histological examination of the tumour that its malignancy was recognised. Cases in the first category, with their attacks of paroxysmal hypertension, have been exhaustively reported, and of recent years a high proportion have probably been diagnosed on clinical criteria alone. It is in the second group—where there is persistent hypertension—that the new diagnostic tests, to be reviewed below, may prove of special value in revealing cases which would otherwise have gone unrecognised, except perhaps at autopsy.

In the typical paroxysm there is a sudden generalised vasoconstriction, together with other symptoms pointing to overactivity of adrenergic nerve-fibres. Usually because of the generalised action of the pressor substance —whether it be adrenaline or noradrenaline—symptoms and signs arise in many parts of the body, but more occasionally the main features are localised symptoms such as epigastric pain, vomiting, diarrhœa, headache, vertigo, paræsthesiæ, cramps, or anginal pain. The attack may be preceded by an aura, *often in the form* of one of these localised symptoms. In some cases the paroxysms are mild, with fatigue, lassitude, and anxiety as the salient features; but more commonly the patient develops palpitations, followed rapidly by nausea, profuse perspiration, a feeling of fullness in the neck, "goose-flesh" and coldness of the extremities, throbbing in the temples, dizziness, and finally a severe headache which persists as the other symptoms subside. This rapid march of symptoms in a restless, anxious patient gives a dramatic and revealing picture. The pulse is usually rapid and often weak and small, but varies from case to case and even from attack to attack; the heart-beat is extremely forcible, and the second sound in the aortic area increased in intensity. Within a few moments the systolic blood-pressure may increase from 120 to 300 mm. Hg with a corresponding rise in the diastolic level, though the *reading* may vary widely during a single attack. Acute pulmonary œdema, retinal congestion, and hæmorrhages have been described, and the pupils are usually widely dilated; there may be hyperglycæmia and glycosuria, and the sugar-tolerance curve may be diabetic in character.

The duration of attacks varies widely. Commonly they last one to two hours and leave the patient relieved but prostrated; but Hyman and Mencher (1943) described a paroxysm lasting thirty-six hours, and van Goidsenhoven and Appelman (1934) one continuing for three days. Between attacks the patients usually feel well, though lassitude, loss of weight, and slight œdema have been reported; and in some the resting blood-pressure is high. Indeed it seems likely that many cases, if undiagnosed, progress to continuous hypertension (Green 1946).

Precipitating Factors

Attacks may arise spontaneously or in relation to the normal adrenaline-production mechanism of emotion, such as fear, anger, excitement, and have also been produced by hyperventilation or change in posture, the latter being probably the most common exciting factor; in the case reported below attacks often developed when the patient lay down at night. Sharp blows on the abdomen, pressure in the renal area, and immersion of the extremities in cold water have all been described as producing attacks.

Death

The common causes of death in these cases are a cerebral vascular accident, during a paroxysm, acute pulmonary œdema, or, in undiagnosed cases, collapse after a minor operation. Less common causes are hypertensive cardiac failure or renal failure, while malignant cachexia and possibly Addison's disease are much rarer terminations.

Electrocardiographic Findings

These are varied, left axis deviation being the most usual single finding. The T waves may be inverted for some weeks after an attack, and the ST interval is commonly prolonged.

DIAGNOSIS

When there are typical attacks the diagnosis is self-evident, but in the absence of paroxysms or a typical history the problem is more difficult. Widely varying blood-pressure readings have been noted in essential hypertension, particularly at the menopause, lead poisoning, eclampsia, tabes dorsalis, angina pectoris, and many other conditions (Mac Keith 1944). The disorder may also resemble thyrotoxicosis, nephritis, migraine, intracranial tumour, angina pectoris, anxiety state, or the vasovagal attacks of Gowers (1907). Cases with persistent hypertension are hard to distinguish from essential hypertension. However, serial blood-pressure readings and pulse records and careful clinical observation, particularly for other signs of sympathetic overactivity, will usually yield, if not a positive diagnosis, at least suspicion; and when his suspicion is aroused the physician may apply one of the following diagnostic tests.

Diagnostic Tests

The diagnosis of phæochromocytoma is proved if increased adrenaline in the circulating blood can be demonstrated; but this increase is not always found (Biskind et al. 1941). Perhaps a more reliable indication is the rise in serum-potassium during the paroxysms (Blacklock et al. 1947).

The test developed by Roth and Kvale (1945) is said to be infallible; it was evolved by means of experiments on 51 subjects, of whom 4 were believed to have a phæochromocytoma.

> The patient lay down and the blood-pressure was read repeatedly. After about half an hour 0·025–0·05 mg. of histamine diphosphate in 0·025–0·05 ml. of physiological saline was injected *intravenously. In normal or hypertensive* subjects this produced a slight rise in blood-pressure, less than that produced by the cold pressor test; whereas in a case of phæochromocytoma the blood-pressure rose about 100 mm. Hg within five minutes and a typical paroxysm was provoked.

The main disadvantage of this test is that it induces a further attack in an already ill patient.

A similar test has been evolved by Guarneri and Evans (1948) on the basis of one case in which subcutaneous injection of 25 mg. of 'Mecholyl' (acetyl-β-methylcholine chloride) caused a sharp rise in blood-pressure, in contrast to a fall in normal persons.

Goldenberg et al. (1947), as a result of tests on 58 subjects, have recommended the use of '933F' (piperidyl-methyl benzodiozane), an adrenolytic agent which, when injected in a dosage of 0·25 mg. per kg. body-weight, caused a fall of at least 50 mm. Hg in blood-pressure during a paroxysm. This test is specific for an increase of adrenaline in the circulation, is very sensitive, and is negative in essential hypertensives. It enabled Goldenberg and his colleagues to suspect a second tumour in a patient from whom one had already been removed. The test is not likely to work, however, where noradrenaline is the pressor agent concerned (Holton 1949).

More recently Spear and Griswold (1948) have evolved a further test with another adrenolytic agent, dibenamine hydrochloride (dibenzyl-β-chlorethylamine hydrochloride), which is given intravenously, over an hour, in a dosage of 7 mg. per kg. body-weight diluted in 300 ml of 5% glucose in physiological saline. This produced a fall of over 50 mm. Hg in blood-pressure during a paroxysm; the fall lasted for twenty-four hours and symptoms were relieved for seventy-two hours. The histamine test was negative six hours after the injection and was still not strongly positive thirty and forty-eight hours afterwards. As with 933F, this test gives no reaction in patients with essential hypertension, or between paroxysms if the resting level of blood-pressure is low.

Yet another test has been described by LaDue et al (1948). The effect of the tetraethylammonium ion in blocking autonomic ganglia is now well recognised, and among others Fisher (1949) has shown that in patients with essential hypertension the injection of 300–500 mg. of tetraethylammonium chloride causes a fall in blood-pressure. LaDue et al. found that in their case of phæochromocytoma the histamine test precipitated an uncontrollable paroxysm; the intravenous injection of 400 mg. of tetraethylammonium bromide produced an identical paroxysm, but the reaction disappeared when the patient stood up. Probably 40 mg. of pentamethonium iodide intravenously (Arnold and Rosenheim 1949) will give a comparable reaction. The mechanism by which these substances produce a paroxysm is presumably *the same as in the histamine test—namely,* generalised dilatation of arterioles and capillaries, increased vascularity of the tumour, and consequent liberation of pressor substance into the circulation. Because the attack produced is controllable, this test appears to be safer than the histamine test.

Localising the Tumour

In about a third of the cases the tumour is palpable, and pressure on it may then provoke a typical paroxysm. Even where no tumour is palpable pressure may still help in localisation; the test is more likely to succeed if the tumour is on the left side. In fact, however, the tumour seems to have a slight predilection for the right side (Strombeck and Hedberg 1939).

In one case tomography revealed the presence of a growth (Mandl 1947); and intravenous pyelography, followed if necessary by retrograde pyelography, is of great value, since it may show displacement or distortion of one renal pelvis (Biskind et al. 1941).

Perirenal insufflation of air has been recommended, particularly in America (Heath et al. 1941); Hyman and Mencher (1943) has carried out this procedure well over 100 times without ill effect but in view of the possible hazards the method is not generally favoured in this country.

When physical and radiological examinations are negative, an exploratory laparotomy is probably advisable, despite the danger of provoking a severe paroxysm. By laparotomy it is possible not only to *localise* the tumour, but also to determine the condition of the other adrenal.

TREATMENT

The treatment of choice is undoubtedly extirpation of the growth, which despite the dangers of operation should always be attempted; for otherwise the prognosis is poor. Radiotherapy usually has only a palliative effect; but it has been successful in a recurrence after operation (Borras and Meyer Mota 1938). The observations of Espersen and Dahl-Iversen (1946) on the disappearance of symptoms after administration of methylthiouracil have not yet been corroborated. Dibenamine (Spear and Griswold 1948) seems to hold out hope for a palliative medical treatment provided the difficulties in administering it can be overcome: at any rate it is likely to be of great value as a preoperative treatment. Dihydroergocornine (Goetz 1949) also appears to have a future in this field.

In the preparation for operation sedation and avoidance of undue excitement are all-important. For the operation basal bromethol anæsthesia has been recommended (Hyman and Mencher 1943), and Mac Keith (1944) suggests that spinal anæsthesia should be avoided: Biskind et al. (1941), however, could find no evidence that the type of anæsthesia had any bearing on postoperative collapse. Parkins et al. (1938) showed that adrenal cortical extract and salt are of value in combating the circulatory collapse of adrenaline shock; and Biskind et al. advise the use of deoxycortone acetate and salt both before and after operation, though in moderate doses so as to avoid pulmonary œdema.

After preliminary laparotomy (if required), lumbar exploration on the appropriate side, with excision of the 12th rib, is the usual procedure. The tumour should be handled as little as possible: for undue handling has been known to produce a hypertensive paroxysm which may be fatal (Holst 1938). It seems wise to have an intravenous saline infusion running from the start of the operation, since this is a convenient vehicle for intravenous medication. A careful watch should be kept on the blood-pressure and pulse-rate throughout. Immediately after removal of the growth the blood-pressure may fall precipitately, presumably because the arterioles have become accustomed to a high concentration of circulating pressor substance from the tumour, and its sudden removal finds the chromaffin tissue elsewhere (e.g., in the opposite adrenal), which has probably been functionally depressed for some time, unable to answer the demand. Yet almost half the recorded cases have shown no postoperative hypotension.

On general principles the most efficient pressor agent for use after operation seems to be adrenaline, and the injection of this substance intravenously or intramuscularly in oil, is strongly advocated by Biskind et al. and others. Prescott (1944), in his search for the most efficient substance to combat postoperative shock in other conditions, has recalled the work of Freeman et al. (1941). This showed that continuous intravenous infusion of adrenaline causes at first a sharp rise of blood-pressure, followed a few minutes later by a fall to below the original level; ephedrine gives a similar rise for some 10–20 minutes. Of the pressor agents Prescott tested, 'Methedrine' proved the most efficient; in 18 out of 20 subjects an intramuscular injection of 20 mg. produced a rise in blood-pressure lasting for two hours. Thus, if adrenaline and ephedrine fail, methedrine might well be used. Blood-transfusion is also of value in the treatment of postoperative shock (Mac Keith 1944). If hypotension does not develop, or if it responds to treatment, convalescence is uneventful.

Of some 50 cases treated surgically, less than a third have died; and those surviving have shown no untoward sequelæ. Of 27 successful cases reported up to 1944, 24 remained quite well, several having been operated on some years previously. The hazards which may be met in treating this condition are amply demonstrated by the 3 cases described by Holst (1938): one of these patients died of cerebral hæmorrhage before operation; the second died as soon as the tumour was handled; and the third, after successful removal of the growth, succumbed with postoperative hypotension.

CASE-REPORT

A married woman, aged 31, was admitted to the Royal Victoria Infirmary under Dr. A. G. Ogilvie as a medical emergency on July 26, 1949. Her history was vague, since she was a poor witness and made light of what few symptoms she admitted. She had suffered from very severe attacks of asthma until three years before admission, since when she had been completely free. (There was no family history of asthma or other allergic disorders or of endocrine disturbances.) For three years she had had frontal headaches, at first mild and infrequent but recently more severe and occurring almost daily. She had had occasional night sweats, but on the whole had felt reasonably well until three months before admission when she had first noticed swelling of the ankles each evening, disappearing with rest; six weeks before admission she had noticed slight puffiness of the eyes on waking, which subsided during the day. She would not admit to any breathlessness or cough, nor had there been any visual disturbance or urinary symptoms. For four days before admission she had been confined to bed and her œdema had largely disappeared.

On admission she was well developed and did not look acutely ill but was slightly dyspnœic at rest. She had an occasional moist but unproductive cough. Her colour was good, and the skin cool and moist. There was minimal œdema of the ankles, but no puffiness of the face. Her pulse-rate was 110 per min., regular; blood-pressure 170/110 mm. Hg. The neck veins were somewhat distended. The heart was evidently enlarged, the apex-beat being in the 6th interspace $4^{1}/_{2}$ in. from the midline. The cardiac impulse was forcible but there was no thrill; the heart-sounds were loud but normal except for a blowing systolic apical murmur. Examination of the abdomen revealed neither tenderness nor a palpable mass: the liver and spleen could not be felt. The retinæ showed no hæmorrhage or exudates and no pathological changes in the vessels. There was a small pleural effusion on the right side and a few crepitations could be heard at the base of the left lung; there was no evidence of emphysema or of bronchial spasm.

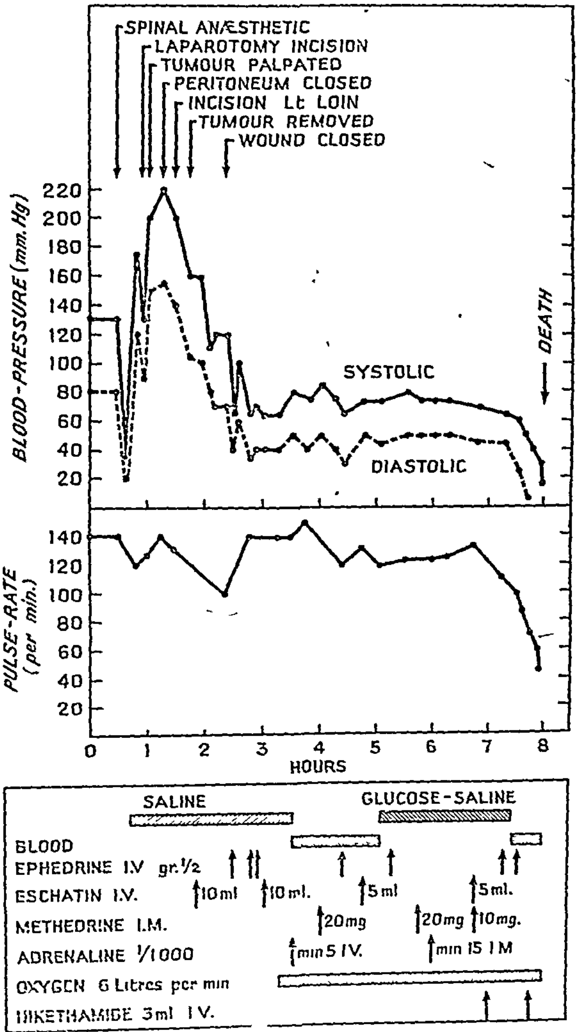
Investigation.—On the clinical findings hypertensive cardiac failure was provisionally diagnosed, and in view of the patient's age a renal basis for the hypertension was sought. Surprisingly, however, the urine contained no albumin or pathological deposit; there was no glycosuria and the blood-urea was 25 mg. per 100 ml. The history of night sweats suggested the possibility of an infective condition, but she was apyrexial on admission; two blood-cultures were sterile: the erythrocyte-sedimentation rate was 8 mm. in one hour (Westergren); and agglutination tests against the enteric organisms, *Brucella abortus* and *Br. melitensis* were all negative. Radiography of the chest confirmed the clinical findings of left ventricular enlargement, right basal effusion, and left basal congestion, and showed no evidence of tuberculosis or other parenchymatous disease. An electrocardiogram showed left axis deviation and inversion of T_2. Hb 83% (12·3 g. per 100 ml.); white-cell count 15,500 per c.mm. on day of admission and 11,000 next day, when the differential count was normal.

Progress.—Investigations had almost reached an impasse, when on July 30, four days after her admission, the patient had a sudden attack in which she perspired profusely, with "gooseflesh," and complained of severe palpitations, followed by a severe "throbbing" frontal and bitemporal headache. Her blood-pressure was not recorded in the attack, but next morning it was 130/80 mm. Hg. In the evening, when she lay down, she had another exactly similar attack; and it was noted, in addition to the features described, that her pupils were widely dilated, her pulse-rate was 140 per min., and her blood-pressure was 280/160 mm. Hg. The blood-sugar in each of two specimens taken during this attack was 130 mg. per 100 ml.

On this clinical picture a diagnosis of phæochromocytoma was made. Further observation of similar attacks left no doubt of the diagnosis, so there was no need to apply the histamine diagnostic test; unfortunately neither the benzodioxanes used by Goldenberg et al. (1947) nor dibenamine were obtainable. Repeated abdominal examination did not reveal any mass, and firm pressure over each renal area in turn did not provoke a paroxysm. Straight X-ray examination of the abdomen and intravenous pyelography gave no definite indication of the side of the lesion. Because of the risk of air embolism, perirenal insufflation of air was not undertaken.

With strict rest in bed and diuresis the patient improved somewhat. The peripheral œdema and chest signs cleared up completely, but she continued to have frequent attacks, usually lasting between half an hour and two hours; these often occurred when she lay down to sleep at night, but occasionally they were provoked by emotion. On Aug. 13 typical gallop-rhythm was heard at the apex, and the left ventricular enlargement was even more pronounced. In view of the uniformly poor prognosis without treatment, and despite the cardiac failure, it was decided that the abdomen should be explored.

Operation.—On Aug. 18, Mr. T. A. Hindmarsh operated. A spinal anæsthetic of·15 ml. of light 'Nupercaine' was given by Dr. M. H. Armstrong Davison through the 2nd–3rd lumbar intervertebral space, after which the patient was kept sitting for a minute before lying down. An intravenous drip of normal saline into the right internal saphenous vein was set up, and light cyclopropane general anæsthesia was begun. The abdomen was explored through a left paramedian incision, and a tumour was found lying in relation to the left adrenal gland and in front of the upper pole of the kidney; the right adrenal gland looked normal. The wound was closed and the patient was turned on to her right side. A further incision was then made in the left lumbar region; the tip of the 12th rib was excised and the kidney exposed. The tumour was found lying in front of the kidney with a bright yellow band of tissue passing across the front of it. It was well encapsulated, and was separated from the left adrenal gland and removed; it was dark brown, spherical, and $2^1/_2$ in. in diameter. The patient's blood-pressure and pulse readings during and after the operation and the drugs given are recorded in the accompanying figure.



Pulse and blood-pressure readings and supportive treatment from the start of operation until death eight hours later.

Unfortunately, despite transfusion, intravenous ephedrine and suprarenal-cortex extract ('Eschatin'), intramuscular methedrine, and small doses of adrenaline, the patient developed postoperative hypotension, which appeared to be irreversible. Peripheral circulatory failure ensued, and she died seven hours later.

Pathology.—Dr. R. Schade reported on the tumour as follows:—"A tumour nodule 5 cm. in diameter and encapsulated. The cut surface shows a rim of yellowish tissue and a hæmorrhagic-looking core. Histological appearances are those of a typical phæochromocytoma."

Autopsy, done by Dr. W. Jack, twelve hours after the patient's death, confirmed that the right adrenal gland was normal. There was no hæmorrhage in the operation site, and no pulmonary œdema. The only finding of note was in the heart, where there was gross dilatation and hypertrophy of the left ventricle.

DISCUSSION

In this case severe postoperative hypotension developed and did not respond to the remedies employed. A point which does not seem to have been noted previously was that the patient, who had suffered severely from asthma, had been completely free from attacks during the development of symptoms of paroxysmal hypertension, presumably owing to autoinoculation with an adrenaline-like substance.

Spinal anæsthesia has been condemned in these cases (e.g., by Mac Keith 1944) because it may cause a fall in blood-pressure; but light spinal anæsthesia has been used successfully (Alwall and Wulff 1948, LaDue et al. 1948), and recommended on the ground that paralysis of the splanchnic nerves during operation might help to prevent an unduly severe paroxysm. It was used in this case because it seemed particularly important to prevent such a paroxysm in a patient who already had advanced cardiac failure. It is doubtful whether the spinal anæsthesia had any bearing on her sustained postoperative hypotension, since she was moving her legs freely and full sensation had returned in them four hours before her death.

Biskind et al. (1941) recommended that adrenaline should always be given if the blood-pressure falls after operation, since this simply replaces the chemical substance to which the body has become accustomed and which has been suddenly withdrawn. In recent years however, it has been questioned whether the pressor agent concerned is always adrenaline. Holton (1949) found large quantities of noradrenaline in 3 typical tumours. West (1947) has shown that noradrenaline is a more efficient pressor agent than adrenaline, and Swan (1949) has confirmed its prolonged pressor effect in healthy males when given intravenously in a dosage of 0·005 mg. per minute. Moreover experimentally, unlike adrenaline, noradrenaline produces a reflex bradycardia; and whereas adrenaline acts by increasing cardiac output (Goldenberg et al. 1949), noradrenaline produces its pressor effect through peripheral vasoconstriction. It may be that some phæochromocytomata produce adrenaline and others noradrenaline, or a combination of the two, as their active principle. This view is supported by the fact that some cases show hyperglycæmia and glycosuria whereas others do not; West (1947) has pointed out that as a hyperglycæmic agent adrenaline is eight times as active as noradrenaline. Thus it may be possible to determine during life which agent is at work, by assaying the substance in the circulating blood or by studying blood-sugar curves, but whatever the answer, it seems that noradrenaline is likely to be a safer and more efficient postoperative agent than adrenaline. Methedrine, as already noted, may be a valuable supplement.

In the present case adrenaline was not used as the mainstay of postoperative treatment because its effect of increasing cardiac output might be dangerous in a patient with severe cardiac failure. Unfortunately noradrenaline was not obtainable; so it was decided to use ephedrine, which had proved successful in the hands of LaDue et al. (1948), and which has a more gradual and prolonged effect than adrenaline (Jackson 1939).

In the reported cases no exact correlation has been found between the severity of the preoperative symptoms and the degree of postoperative shock; but generally the shorter the history the less likely is postoperative shock to develop; so early diagnosis appears to be important in its prevention. The tetraethylammonium-bromide test may prove the safest method of diagnosis where the symptoms are vague or the paroxysms infrequent; dibenamine is likely to be most useful in diagnosing cases where there is persistent hypertension, and in preoperative treatment.

SUMMARY

A fatal case of phæochromocytoma of the left adrenal gland in a woman, aged 31, gave rise to the typical adrenal sympathetic syndrome.

The recent development of several diagnostic tests, which are described, has led to the recognition of many more examples of this condition during life.

Dibenamine is likely to be of value as a preoperative agent.

Some of the tumours may produce their symptoms and signs by the secretion of adrenaline, whereas others secrete noradrenaline or a combination of the two; but it is suggested that noradrenaline rather than adrenaline should be used for the treatment of postoperative hypotension.

I am grateful to Dr. A. G. Ogilvie for permission to publish the case; the late Mr. Hindmarsh for allowing me to use his operation notes; Dr. Armstrong Davison for the record of anæsthesia; and Dr. Schade and Dr. Jack for pathological data. I am also indebted to Dr. H. G. Miller and Dr. I. O. B. Spencer for advice; and to Dr. J. D. Sinson and Mr. J. Andrews for assistance.

TUBERCULOUS SINUSES TREATED WITH STREPTOMYCIN LOCALLY

R. T. AHERN
M.B. N.U.I., D.P.H.
ASSISTANT SURGEON AND DEPUTY SURGEON-SUPERINTENDENT, HEATHERWOOD HOSPITAL, ASCOT

THE tragedy of secondarily infected tuberculous sinuses is a familiar one to surgeons, and fifteen years or more ago, in pre-sulphonamide days, most large surgical wards had their quota of emaciated pyrexial patients with profusely discharging sinuses. Death was the usual outcome, especially when the lower spine or sacro-iliac joints were affected. Free drainage was the only applicable treatment at the time, and even with this many cases continued to go downhill. The sulphonamides effected healing in the odd case and some improvement in others, but the problem was by no means solved. With the advent of penicillin the prognosis was further improved, but a disappointing number of cases still showed little or no response.

I describe here the results obtained in 25 cases of bone and joint tuberculosis with sinuses which were treated by the local instillation of streptomycin. In some cases the antibiotic was also given intramuscularly for short periods. The primary object of streptomycin treatment was to combat the secondary infection, and no direct effect on the underlying tuberculous infection is claimed. It may well be, however, that the bacteriostatic action of streptomycin on tubercle bacilli had an important bearing on the results, since it is otherwise difficult to explain why penicillin therapy had no effect in some of these cases where the organisms were penicillin-sensitive and where penicillinase was unlikely to be present.

The patients treated can conveniently be divided into the 8 who were critically ill, as a result of either a severe toxæmia with profuse discharge and high temperature or long-standing suppuration lasting two years or more with the attendant risk of amyloid disease; and the remaining 17, who had sinuses associated mostly with the joints of the extremities and could not be regarded as seriously ill. Of the critically ill group, 7 cases are described here in detail.

Case 1.—A man, aged 20, admitted to Heatherwood Hospital on July 19, 1948, responded so favourably to local instillations of streptomycin that this treatment was adopted in all subsequent cases.

On admission the patient had a profusely discharging sinus in the right iliac fossa, and evening pyrexia of 100–102°F. Radiography revealed a variable amount of narrowing of the intervertebral discs from D6 to L1 and slight erosion of the anterior surfaces of vertebræ D11 and 12. A minute area of tuberculous infiltration showing evidence of healing was seen in the upper zone of the left lung. Culture of pus from the sinus gave a growth of *Staph. aureus* and a few diphtheroids. The staphylococci were penicillin-sensitive and coagulase-positive, yet there was no response whatsoever to repeated courses of penicillin and sulphonamides.

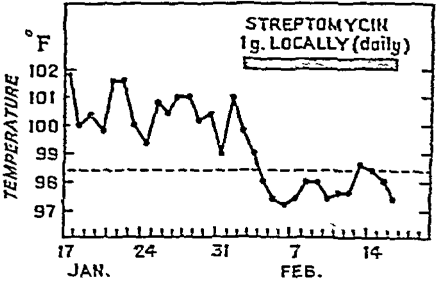

Fig. 1—6 p.m. temperature chart of case 1, showing immediate response to daily instillation of streptomycin into sinus.

Induration, thickening, and tenderness were noted in the left iliac fossa in September, 1948, and a cold abscess developed in the right loin in November, 1948. A course of streptomycin was begun on Dec. 3, 0·5 g. being given intramuscularly b.d. for twenty days. The dosage was increased to 1 g. b.d. for a further five days and was then discontinued because no improvement was observed. On Jan. 21, 1949, abscesses in the left iliac fossa and right loin were incised, but still there was no improvement; the man had lost 22 lb. since admission, and a bad prognosis was given.

The local application of streptomycin was begun on Feb. 2, 1 g. dissolved in 5 ml. of physiological saline solution being instilled with a fine catheter into the sinuses once daily. The result was dramatic and unexpected. Within twenty-four hours the patient's temperature dropped to within normal limits and never rose subsequently (fig. 1).

This treatment was continued until April 9, and all three sinuses were healed by April 12. The patient volunteered that he felt a new man from the first instillation, and it is worth noting that subsequent patients of a similar type all commented on their sense of well-being from the very start of treatment.

On June 6 the scars in the left iliac fossa and right loin again broke down, and another course of local streptomycin was begun on the 14th. On the 15th right-sided epididymectomy was done for tuberculous disease. By Aug. 3 all the sinuses were soundly healed, streptomycin having been discontinued three days before. There had been neither pyrexia nor deterioration in the patient's general condition throughout this latter period. His weight had increased by 34 lb. between January and July, 1949, and he was discharged on Aug. 14. The erythrocyte-sedimentation rate (E.S.R.) before discharge was 4/200 mm. (Westergren) in the 1st hour.

The patient was seen as an outpatient on Oct. 1, 1949, when his general condition was excellent and all his sinuses had soundly healed.

Case 2.—A man, aged 24, was admitted to Heatherwood Hospital on March 11, 1949, with erosion of the fourth and fifth lumbar vertebræ and a right psoas abscess which had already tracked into the thigh and involved the skin. A sinus formed here early in April, and towards the end of the month the discharge had much increased and the patient's evening temperature was 101°F. Culture of the pus on May 3 gave a heavy growth of *Staph. aureus* coagulase-positive and sensitive to penicillin and streptomycin.

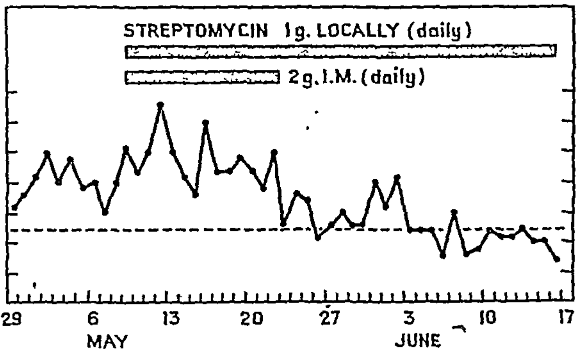

Fig. 2—6 p.m. temperature chart of case 2, showing delayed response, probably because of defective drainage.

No improvement followed two weeks' penicillin therapy. Streptomycin was given from May 9 onwards; 0·5 g. was given intramuscularly six-hourly for a fortnight, and 1 g. was instilled once daily into the sinus until July 23. The sinus healed by July 26. The temperature was slow to settle and did not reach normal limits until twenty-five days after the start of treatment (fig. 2); this was probably because drainage was not entirely adequate.

Absorption from the sinus track was rapid, a blood-streptomycin level of 64 µg. per ml. being attained an hour after the instillation of 1 g. Culture from a swab taken shortly before healing gave a pure growth of diphtheroids.

On Oct. 31, 1949, the patient's sinus was still healed. The E.S.R. was 2/200 mm. in the 1st hour.

Case 3.—A woman, aged 28, underwent protracted conservative treatment at Heatherwood Hospital from March, 1945, to July, 1949, in the first instance for a lesion of her first and second lumbar vertebræ, and for tuberculous arthritis of the right hip which developed in January, 1947. Tubercle bacilli were grown repeatedly from pus aspirated from cold abscesses. A sinus formed in the right loin in May, 1947, and in the right groin in August, 1947. Increased discharge and evening pyrexia of 99–101°F were noted from August onwards. No improvement took place with penicillin or sulphonamides.

On Feb. 14, 1949, streptomycin treatment was begun by local instillation into the sinuses, 0·5 g. being given b.d. This was changed to 1 g. once daily from March 1 onwards. A five-day course of intramuscular streptomycin was also given from Feb. 17. An abscess in the left loin was incised on Feb. 23, and on March 3 and 4 a very copious discharge was noted, presumably from a pocket which had not been drained at the time of the incision. On March 3 pus from the sinus gave a growth of coagulase-positive *Staph. aureus*. The improvement subsequently was dramatic. All three sinuses were healed by April 1, three days after streptomycin had been discontinued.

The patient was discharged home on July 14, and when she was seen as an outpatient on Oct. 1 her sinuses were still soundly healed.

Case 4.—A man, aged 28, first developed a sinus in the right iliac fossa in 1935. Spinal fusion was done in 1936 for a lesion of vertebræ L4–S1 some time after the sinus had healed. Soon after this operation sinuses formed in the right iliac fossa and left loin and persisted. The patient was admitted to hospital on Nov. 5, 1948, with increased discharge from the sinuses and diarrhœa with pus and blood in the stools. Culture of pus from the sinuses gave a growth of coagulase-positive *Staph. aureus*. Radiography after barium enemata and instillation of an opaque dye into the sinuses showed a track leading towards the fifth lumbar vertebra but no connection with the gut. On Jan. 3, 1949, the sinus in the right iliac fossa was explored and found to lead to an abscess cavity in the right flank which extended towards the fifth lumbar vertebra and did not communicate with the pelvis or gut. Healing did not take place with protracted penicillin therapy from November, 1948, to March, 1949.

On admission to Heatherwood Hospital, on March 13, 1949, he was apyrexial. There was a moderate amount of purulent discharge from the sinus in the right iliac fossa and slight discharge from the sinus in the left loin. Healing followed local instillations of streptomycin 1 g. once daily into the sinuses for eight weeks. The E.S.R. was 2/200 mm. in the 1st hour on the patient's discharge from hospital on May 19, 1949.

Follow-up.—The patient re-attended as an outpatient on June 26, 1949, because the scar in the right iliac fossa had broken down. No deep track could be found. A patchy urticarial type of skin reaction was present, especially round the sinus. Culture from a swab showed a heavy growth of hæmolytic streptococci and coagulase-positive *Staph. aureus*. Both organisms were streptomycin-sensitive. The skin reaction abated and the sinus healed within two weeks with a course of 'Benadryl.'

When the patient was seen as an outpatient on Oct. 1 both sinuses were soundly healed.

Case 5.—A man, aged 29, with tuberculosis of the right sacro-iliac joint since 1942, underwent two long periods of conservative inpatient treatment at Heatherwood Hospital from August, 1942, to June, 1945, and from September, 1945, to March, 1947. Erosion of the left sacro-iliac joint was noted in August, 1943. A sinus first formed in April, 1943, in the right thigh, and on the patient's readmission in September, 1945, multiple sinuses were present in both thighs and iliac fossæ. The response to sulphonamides and penicillin was disappointing, and the sinuses persisted. The patient continued to be seen at aftercare clinics, and in October, 1948, his liver was found to be extended two finger-breadths below the costal margin. In March, 1949, the general picture was that of moderately advanced amyloid disease, and the liver had enlarged still further.

The patient was readmitted to hospital in April, 1949, for streptomycin therapy. Pus from a sinus showed gram-positive cocci, and culture gave a growth of coagulase-positive *Staph. albus*. Intramuscular streptomycin 0·5 g. was given six-hourly from April 21 to May 17. Local instillations of 1 g. once daily were started at the same time and continued until final healing took place on July 5, 1949.

In this case, however, a sinus persisted in each thigh and seemed unlikely to heal under streptomycin therapy alone. On May 30 these sinuses were explored. The entire track, about 4 in. long, on the left side was excised. The wound healed by first intention. The sinus on the opposite side communicated with a large pocket in the buttock. This was curetted and left open, and streptomycin instillations were continued until healing took place. The E.S.R. fell from 80/200 to 26/200 mm. in July. Albuminuria was occasionally present up to the patient's discharge from hospital in August, 1949.

When the patient was seen as an outpatient on Nov. 15, 1949, *all the sinuses* were *soundly healed.*

Case 6.—A man, aged 26, underwent twenty-three months' conservative treatment from 1943 to 1945 for caries of the fourth and fifth lumbar vertebræ and the right sacro-iliac joint. A sinus was present in the left buttock when the patient *left hospital in 1945*, and more sinuses formed in 1946 and 1947. The patient was readmitted to Heatherwood Hospital in September, 1947, with multiple sinuses. He was mildly pyrexial. The amount of discharge decreased considerably with a twelve-day course of penicillin. In November, *1947, the discharge became very offensive and a communication* with the lower bowel was suspected. Radiography after instillation of iodised oil into the sinuses was inconclusive. *Staph. aureus* was grown from the pus in April and June, 1948, the organisms on each occasion being non-sensitive to penicillin. A slight improvement, however, followed a week's course of penicillin in June, 1948. Sigmoidoscopy on Sept. 24, 1948, did not reveal any abnormality. A course of *p*-aminosalicylic acid started on Dec. 1, 1948, led to some improvement but had to be discontinued after eighteen days because of nausea and vomiting.

On Feb. 12, 1949, streptomycin therapy was begun, by the instillation of 1 g. once daily into the sinuses. By May 5 the sinuses were reduced to two at the back, and the treatment was discontinued because of effusions into the knee-joints and ankle-joints. At the time the patient was up and about. No cause for the effusions was found, and they rapidly subsided with rest. Streptomycin treatment was begun again on June 11. One sinus healed in four days and the other was curetted on June 23, 1949. The instillations were continued, and healing took place by mid-July. The *patient gained* 28 *lb. in weight* between *February and* July. The E.S.R. was 7/200 mm. in the 1st hour shortly before the patient's discharge from hospital on July 24, 1949. Two sinuses re-formed about 6 weeks later, and a further course of streptomycin was started, with the patient as an inpatient, on Oct. 3, 1949, both by *intramuscular injection* of 0·5 g. six-hourly and 1 g. once daily into the sinuses. The intramuscular streptomycin was discontinued on Nov. 1. By Nov. 10 both sinuses were healed.

Case 7.—A man, aged 35, was admitted to Heatherwood Hospital on May 4, 1948, with reactivated disease of vertebræ D10–12. A sinus formed in the right lumbar region a month later. Early in August there was evidence of secondary infection, with a rise of temperature and increased purulent discharge from the sinus. Penicillin was ineffective. On Aug. 9 culture of the pus gave a growth of coagulase-positive *Staph. aureus* insensitive to penicillin. On Aug. 14 tenderness and deep fluctuation were noted in the left iliac fossa. A large lumbar abscess had formed by Aug. 23. This was incised and gave adequate drainage. Some improvement followed, but the sinuses in both lumbar regions persisted and the *patient continued* to be mildly pyrexial. A course of sulphathiazole had no effect, and on Dec. 20, 1948, intramuscular streptomycin was begun, 0·5 g. being given b.d. for eight days and then 1 g. b.d. until Jan. 11, 1949. On Dec. 20 a course of local streptomycin 1 g. once daily was also begun.

Healing was rapid, but the sinus on the left side broke down twice subsequently. The *streptomycin in this case* seemed to facilitate rapid surface healing, but deep suppuration still continued. Intramuscular injections of 1 g. b.d. were begun on March 26, 1949, and changed to 0·5 g. six-hourly on April 8. By the end of the month the sinus had soundly healed, and treatment was discontinued on May 6.

The sinuses were still soundly healed in October, 1949.

The remaining 18 cases can be dismissed briefly. All were treated with local instillations alone of 0·25–1·0 g. once daily, the dose depending on the extent of the sinus, and the sinuses healed in periods *ranging from* two weeks to four months. Sequestrectomy was done in one patient with disease of a hip-joint and great trochanter on the same side, while streptomycin treatment was also being given; the removal of *two sequestra* seemed to hasten healing. In only one other case was healing aided by surgery. This was in a man with a small lumbar sinus associated with spinal disease; streptomycin alone seemed to have little effect, but healing took place a week after *curettage* of the track. In only 1 of the 18 cases did a sinus break down and persist. This was in a woman with spinal caries who had two sinuses which healed with difficulty after four months' treatment; when she was seen subsequently at an aftercare clinic one sinus had formed again; so far she has not had a second course of streptomycin.

The underlying tuberculous foci in these 18 cases were *as follows:*

Foci	*Cases*
Spine	5
Hip-joint	3
Knee-joint	2
Ankle-joint	1
Shoulder-joint	1
Os calcis	2
Costochondral junctions	2
Hip-joint and great trochanter (same side)	1
Shoulder-joint and ankle-joint	1

DISCUSSION

It is instructive to compare these results with those obtained by others with systemic streptomycin. In the U.S.A. Brock (1948) treated 12 patients with 60 sinuses in this way, and 11 of the 12 cases showed striking *improvement; half the sinuses healed* within ten to twelve weeks and all had healed after twenty weeks. The method of administration was by intramuscular injection of 0·3 g. four-hourly for ninety to a hundred and fifty days. A blood-level of 10–20 µg. per ml. was attained two hours after injection. In another American paper, Bickel et al. (1948) reported on 16 cases of bone and joint tuberculosis treated with systemic streptomycin. Sinuses were present in 11 of the cases and, judging *from the individual reports, the sinuses appear to have* healed in 3 cases as a direct result of streptomycin therapy. Varying degrees of improvements were noted in others, but in 2 cases there was no response. The general line of treatment was intramuscular injection of 0·75–2 g. *daily in 2–4 doses for ninety* to a hundred and twenty days. From the North Wales Sanatorium Davis (1949) lately reported on 11 cases with 28 sinuses, 5 of which had originated in bone and joint. The dosage of streptomycin he adopted was usually 1 g. once a day intramuscularly, the total dose depending on the response. Of the 28 sinuses, 21 healed within three months and the remainder after three months.

With systemic administration the aim is to maintain what *is generally considered to* be an effective bacteriostatic blood-streptomycin level, but a very high concentration of the antibiotic localised to the region where it is most required, even though this is maintained for only a relatively short period in the 24 hours, seems to be at least equally efficacious. The streptomycin introduced into a sinus is rapidly absorbed into the blood-stream, and, as would be expected, the more recent the sinus the more rapid the absorption. Two examples will illustrate this point. In case 2 a blood-level of 64 µg. per ml. was attained an hour after 1 g. had been given locally. Another patient, with tuberculosis of the spine and ribs (a recent admission not included in this series), had had sinuses of the chest wall for more than four years. Blood-levels of 28, 10, and 0 *µg. per ml.* were *attained one, four, and eight* hours after the introduction of 1 g. of streptomycin locally into the sinuses.

Some of the experimental work supports the view that streptomycin may benefit the patient's clinical condition *even though* a bacteriostatic concentration of *the antibiotic is* not maintained during the treatment period. Thus guineapigs infected with tuberculosis after a course of streptomycin lived on an average 29 days longer than animals not so treated.

A strong argument in favour of treating tuberculous sinuses with streptomycin administered locally through a fine catheter is that the treatment is painless and causes no reaction in the surrounding tissues. This is of considerable importance when the antibiotic has to be given for perhaps three months or more.

SUMMARY

The results obtained in 25 cases of bone and joint tuberculosis with sinuses treated by local installation of streptomycin are described and compared with the results of intramuscular injection.

A continuous bacteriostatic blood-level is not essential for a satisfactory clinical result.

An important advantage of local installation is that it is painless; it also seems to be more effective than intramuscular injection.

I wish to thank Mr. L. A. Key for many helpful suggestions, and Dr. F. E. T. Scott for performing all the laboratory investigations.

PENICILLIN-RESISTANT STAPHYLOCOCCI

INCIDENCE IN RELATION TO LENGTH OF STAY IN HOSPITAL

H. J. F. Cairns
B.M. Oxfd

G. A. C. Summers
B.Sc., M.B. Edin.

From the Department of Bacteriology, the Radcliffe Infirmary, Oxford

Barber et al. (1949) and others have reported an increasing preponderance of penicillin-resistant strains among the pyogenic staphylococci isolated from infections arising in hospital. By carrier surveys and phage-typing, these have been related to penicillin-resistant strains among the doctors and nurses.

We have tried to ascertain how closely infection with penicillin-resistant strains is related to the length of time spent in hospital. The strains investigated were coagulase-positive as tested by the tube method, and for present purposes we divide them broadly into sensitive and resistant categories according to their reaction on a penicillin-gutter plate (Fleming 1942), containing one unit of penicillin per ml. of agar in the gutter. This reaction provides a clear-cut division. In the rare cases where more than one strain was isolated from the same specimen, the most resistant strain was selected for the analysis.

Of 417 inpatients from whom strains of *Staphylococcus pyogenes* were obtained, 326 had records showing how long they had been in hospital before the organism was isolated, and (in the case of the 139 who were receiving systemic penicillin) the duration of penicillin treatment before its isolation. These 326 patients were divided into the following groups:

1. Infections arising in hospital.
2. Open infections, present on admission and susceptible to cross-infection.
3. Closed abscesses, present on admission.
4. *Cases where the infecting rôle of the staphylococcus was doubtful.*
5. Cases where no infection was present (e.g., routine nasal swabs).

TABLE I—PROPORTION OF PENICILLIN-RESISTANT STRAINS OF *Staph. pyogenes* ISOLATED FROM 326 INPATIENTS

Group of patients	Total strains	% resistant	χ^2	P
Closed infections ..	70	19	11.00	<0 001
Open infections	103	43	0 13	0 72
Possible infections ..	57	46	1·71	0·19
Uninfected	28	61	2 98	0 08
Hospital infections ..	68	78		
Total ..	326	—	—	—

For the table as a whole, $\chi^2 = 51\ 77$, P = <0 001.

TABLE II—PROPORTION OF PENICILLIN-RESISTANT STRAINS AND ITS RELATION TO THE DURATION OF STAY IN HOSPITAL OF 103 PATIENTS ADMITTED WITH OPEN INFECTIONS

Time in hospital	*Total strains*	% resistant	χ^2	P
0–1 day ..	51	25	5·42	0 02
2–7 days ..	27	52	1·41	0 23
8 + days ..	25	68		

For the table as a whole, $\chi^2 = 13\ 63$, P = 0 001.

These five groups show conspicuous differences in the proportion of penicillin-resistant strains isolated (table I). The high incidence of resistance in infections arising in hospital is well recognised (Barber and Rozwadowska-Dowzenko 1948). The difference between the closed and the open infections which were present on admission to hospital is interesting, however, because similar proportions of the two groups had had penicillin therapy of comparable duration. Either poor access of penicillin or the absence of cross-infection could account for the significantly smaller number of resistant strains *isolated from the closed group. Support for the latter* explanation is gained from further study of the open infections. These were made up as follows:

Infected-fingers, hands, &c.	23
Skin infections	19
Otitis media	15
Otitis externa	4
Wound infections (not arising in hospital) ..	9
Cutaneous ulcers	7
Draining abscesses	7
Antral and sinus infections	8
Conjunctivitis	6
Miscellaneous	5
Total	103

Table II shows that, with increasing time in hospital, the proportion of resistant strains rose, so that after the first week in hospital these open cases were almost indis*tinguishable, in respect of penicillin* resistance, from infections arising in hospital (68% and 78% providing resistant strains, respectively). That this effect is not due to treatment with penicillin is shown in table III, where the correlation is seen to be with the time spent in hospital rather than with the presence or absence of previous penicillin therapy.

TABLE III—RELATION BETWEEN PENICILLIN THERAPY, TIME IN HOSPITAL, AND THE PROPORTION OF PENICILLIN-RESISTANT STRAINS (EXPRESSED AS FRACTION OF TOTAL STRAINS IN EACH GROUP) IN 103 PATIENTS ADMITTED WITH OPEN INFECTIONS

Treatment	*Time in hospital*		
	0–1 day	2 + days	Total
No penicillin ..	9/28	12/22	21/50
Penicillin ..	4/23	19/30	23/53
Total ..	13/51	31/52	44/103

CONCLUSIONS

Our results seem to show that, in staphylococcal infections treated with penicillin, resistant strains would rarely emerge if cross-infection were avoided. They also show how rapidly this cross-infection occurs in hospital.

We hope to publish separately the section of this work dealing with the outpatients, who made up the balance *of 1000 cases studied.*

We wish to thank Mr. R. L. Vollum, D.PHIL., for constant encouragement at all stages of the work, and Mr. *D. J. Finney for advice* on the treatment of some of the data.

PURE ANTI-E ANTIBODY IN THE SERUM OF A Rh-POSITIVE WOMAN

ELUNED M. STEVEN
M.B. Lond., D.Obst. R.C.O.G., D.C.H.
ASSISTANT PÆDIATRICIAN, ELSIE INGLIS MEMORIAL HOSPITAL, EDINBURGH

THIS is a report of a case of icterus gravis with kernicterus in a Rh-positive baby whose parents were both Rh-positive. The cause was a pure anti-E antibody found in the mother's blood.

CASE-RECORD

The mother, aged 26, had been married $5\frac{1}{2}$ years and had one child, a daughter born in 1945, who is alive and well. She had had no miscarriages or blood-transfusions. In December, 1948, she attended the antenatal clinic, being then two months pregnant. At this stage her blood was reported as group B, Rh-positive; Wassermann negative; hæmoglobin 80%. Her health antenatally was good with no toxæmic symptoms.

A female baby was born spontaneously on June 3, 1949 (expected date of delivery June 27). The liquor was normal in colour and the placenta healthy, weighing 26 oz. At birth the baby was vigorous and of healthy appearance and weighed 8 lb. Eight hours after birth the baby was slightly jaundiced, her liver and spleen were not palpable, her hæmoglobin was 140% (Sahli), her red-cell count was 4,000,000 per c.mm., a blood film showed 8 nucleated red cells per 100 white cells and there was no bile in the urine.

June 4.—Jaundice deeper but baby sucking well and quite lively. Hb 134%, red cells 4,000,000 per c.mm. Coombs test weakly positive. Liver and spleen still not palpable. Blood film showed 6 nucleated red cells per 100 white cells.

June 5.—Jaundice very deep and baby more drowsy, with cerebral cry and some opisthotonos. Hb 100%, falling to 82% by the end of the day, red cells 4,230,000 and white cells 8200 per c. mm. Fluids still taken well. Blood film showed 3 nucleated red cells per 100 white cells.

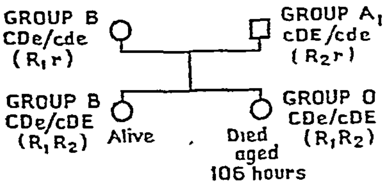
June 6.—Jaundice unchanged. Hb 80%, red cells 3,000,000 per c.mm., icteric index 50 (normal 42. Smith 1946). Baby had high-pitched cry and well-marked opisthotonos.

June 7.—Baby died with signs of severe kernicterus. Hb 94%, red cells 4,260,000 and white cells 10,800 per c.mm. Blood film showed 13 nucleated cells per 100 white cells.

The mother's breast-milk and saliva were tested for Rh antibodies, but none were detected.

Necropsy

The post-mortem appearances were those of a typical case of hæmolytic disease of the newborn (icterus gravis), with enlarged liver and spleen. The meninges and brain showed general yellowish staining, and there was very severe nuclear jaundice. The grey matter of the cervical cord was also intensely stained. A blood film showed 23 nucleated red cells per 100 white cells, all late normoblasts except for one early normoblast. A bone-marrow film showed active cellular marrow with erythropoiesis of average amount and normal type and with no undue proportion of early forms of nucleated red cells.



Genotypes of the family.

The genotypes of this family are shown in the accompanying figure.

DISCUSSION

The interest of this case lies, first, in the presence in the mother's blood of pure anti-E antibody. With the exception of anti-D, single agglutinin anti-Rh sera are relatively rare; about 1% of anti-Rh sera are said to contain anti-E alone (Mollison et al. 1948). I have been able to trace very few published reports of similar cases: two are mentioned by Race et al. (1943), one by Race (1946), one by Diamond and Abelson (1945), two by Wiener et al. (1945) in Rh-positive mothers, and Dick (1947) has recorded a case in a Rh-negative woman.

Since the mother in my case was Rh-positive, antibodies were not looked for antenatally, but subsequent tests revealed a blocking antibody for E agglutinin, with a titre of 1/16, and also a weak saline antibody.

The second point of interest is that there seems to be no reliable means of deciding the form of treatment in such cases, when the baby is clinically normal at birth and the blood picture is within normal limits.

The main evidence that this baby was liable to be severely affected was the early onset of jaundice; but there is no criterion by which one can judge whether the disease will develop simply into a mild anæmia or will proceed to damage of the brain. Jaundice alone is insufficient to justify exchange transfusion in the hope of preventing the possible development of kernicterus. Mollison and Cutbush (1949) suggest that the hæmoglobin and bilirubin of the cord blood may provide the most helpful aids to prognosis, but in this case these data were not known. They also found erythroblastæmia in all their moderate and severe cases, but this did not develop in the present case.

I wish to thank Dr. A. Macgregor, of the Royal Hospital for Sick Children, Edinburgh, for the necropsy findings, Dr. R. A. Cumming for the serological findings, and both them and Dr. M. Martin, of the Elsie Inglis Memorial Hospital, for their interest and advice.

POTASSIUM DEFICIENCY IN *p*-AMINOSALICYLIC ACID THERAPY

CARDIAC AND PARALYTIC EFFECTS

F. E. DE W. CAYLEY
M.B.E., M.D. Lond., M.R.C.P.
SENIOR REGISTRAR, ST. STEPHEN'S HOSPITAL, LONDON

IN patients with pulmonary tuberculosis under treatment with *p*-aminosalicylic acid (P.A.S.) the serum-potassium may be dangerously lowered. Two examples are described below, one patient developing cardiac irregularities and the other a symmetrical paralysis of the hands. In a third case (case 1) the serum-potassium level was not estimated but the cardiac irregularities present may well have resulted from the same cause.

CASE-RECORDS

Case 1.—A woman began a course of P.A.S. on June 22, 1949, the dosage in this and subsequent cases being 3 g.

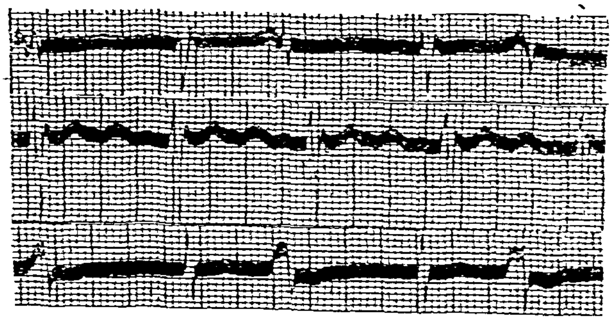

Fig. 1—Electrocardiogram in case 1: alternate normal beats and ventricular extrasystoles.

three-hourly for six doses daily. The only disturbance in the first two months was some vomiting in the evening. On Aug. 9 her blood-P.A.S. level, calculated as the sodium salt, was 10·1 mg. per 100 ml. On Sept. 3, Dr. D'Almero Kok, a registrar, found that the patient had coupled heart beats; and on Sept. 8 an electrocardiogram showed normal beats alternating with ventricular extrasystoles (fig. 1). The blood-P.A.S. level at this time was 9·1 mg. per 100 ml. When P.A.S. was discontinued, on Oct. 1, the coupling of beats ceased. The significance of this was not understood at the time, and the serum-potassium was not estimated.

Case 2.—This woman began a similar course of P.A.S. on Aug. 22. Six weeks later her blood-P.A.S. level was 4·5 mg. per 100 ml. On Sept. 28 her temperature rose to 101°F, and she noticed weakness of her left forefinger, progressing to involve all the fingers of her left hand, and next day her right hand became similarly affected. She was found to have well-marked weakness of dorsiflexion of the left wrist with wrist-drop, and weakness of the extensors of the fingers, interossei, triceps, and deltoid on the left side. The right wrist, fingers, and interossei were more mildly affected. The patient had to be fed. There was no sensory loss, and no cardiac irregularity was observed.

The P.A.S. was discontinued immediately. Because of the resemblance to familial periodic paralysis, the serum-potassium was estimated next day and found to be 13·6 mg. per 100 ml. (normal 16–20 mg.). The blood-count and lumbar-puncture fluid were within normal limits.

The paralysis advanced no further; it began to improve on Oct. 3, and had gone by the 5th. On the 10th the serum-potassium was 20·6 mg. per 100 ml.

Case 3.—This woman started her course of P.A.S. on Sept. 10. A month later she complained of palpitations, and on the morning of Oct. 13 coupled heart beats were felt. An electrocardiogram taken that afternoon, however, showed ordinary sinus rhythm; but there was well-marked depression of the S-T segment in all three leads, with no clear-cut T wave, rather like a digitalis effect (fig. 2). The blood-P.A.S. level at this time was 5 mg. per 100 ml. The serum-potassium was found to be only 11·2 mg. per 100 ml. P.A.S. therapy was *discontinued immediately, and by Oct. 28 the serum-potassium* had risen to 21·5 mg. per 100 ml.

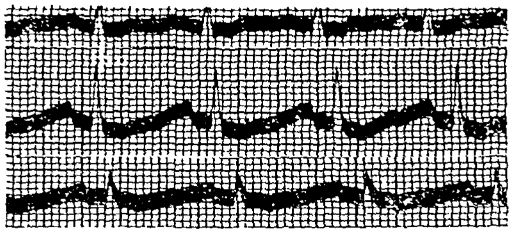

Fig. 2—Electrocardiogram in case 3: *depressed S-T segment with indefinite T wave.*

DISCUSSION

Normal serum-potassium levels have been found in other patients being treated with P.A.S. with no cardiac or neurological symptoms.

The ill effects of potassium deficiency in the blood are fully described by Gass et al.[1] Muscular paralysis from this cause is found in familial periodic paralysis, in patients recovering from diabetic coma, in severe thyrotoxicosis, in chronic nephritis, and after overdosage with deoxycortone. Gass et al. describe the onset of bigeminal rhythm in one of their cases of familial periodic paralysis and have found low T waves in such conditions. The electrocardiographic changes in potassium deficiency resemble those produced by overdosage of digitalis, and it is thought that digitalis affects the intracellular concentration of potassium in the heart. The cause of the muscular paralysis may lie in an inability to release or synthesise acetylcholine at the myoneural junctions.

I wish to thank Dr. A. L. Wingfield for permission to publish these cases and Dr. A. G. Signy for the laboratory findings.

---

New Inventions

A NEW WARM STAGE FOR THE MICROSCOPE

In our laboratory one of us (T. H. N.) has recently designed a thermostatically controlled warm stage, for the microscopical examination of living cells, which we believe has several useful innovations.

(1) The under-surface of the microscope slide (which carries the specimen to be examined on its upper surface beneath a cover-glass) is flush with the under-surface of the warm chamber. Consequently it is possible to bring the substage condenser into contact with the under-surface of the microscope slide. An oil-immersion objective can thus be used at its full numerical aperture, and if required an oil-immersion substage condenser can also be used. So far as we know, this is impossible with other warm chambers.

(2) The warm chamber is made throughout of 'Perspex.' It is therefore transparent and it is possible to see exactly what part of the specimen one is looking at, while the lowering of an oil-immersion objective into the immersion oil is also greatly facilitated.

(3) The chamber, as made, is designed to fit the built-in stage of the standard microscope made by Messrs. Cooke, Troughton, & Simms Ltd. It will also fit the built-in stages of other microscopes of the same pattern. For other types of built-in moving stages it may be necessary to make minor modifications in the various clips, &c., on the upper surface of the moving stage. The chamber cannot be used with the majority of "attachable" moving stages; it can, however, be used when such a stage has been detached, in which case the movements must be controlled directly by hand.

(4) In the roof of the warm chamber is a large circular hole $1^3/_5$ in. in diameter. Covering this aperture is a circular perspex disc, $2^3/_5$ in. in diameter, containing a central hole through which, fitting quite loosely, the object-glass can be inserted. When the warm chamber is moved about by the moving-stage controls, the circular disc slides about on the roof of the chamber, thus providing complete freedom of movement of the chamber and specimen relative to the object-glass without appreciable loss of heat. The dimensions of these various parts are so arranged as to enable the object-glass to travel transversely from one extreme edge of the slide to the other, and longitudinally over at least $1^1/_4$ in., the two movements sufficing to include easily the whole surface of an ordinary cover-slip.

(5) The microscope slide rests in a rectangular hole in the floor of the chamber, just large enough to take the average microscope slide. On one side of this aperture is a spring clip so that when the slide is placed in the aperture it is held rigidly in position. As a result there is no back-lash between the microscope slide and the chamber when the latter is being moved by the moving-stage controls; further, the slide can be placed in the warm chamber when the chamber is detached from the microscope. The chamber can therefore be taken to the patient's bedside and the slide placed in position immediately after the specimen has been obtained. The chamber is then kept warm with a portable battery until it can be placed on the microscope stage and connected to the mains.

(6) The warm stage is heated by an electrical element wound round a glass rod and everywhere insulated from its perspex supports by glass cuffs or glass beads. The current required is either 6 or 8 volts, which can be obtained either from a battery or, more conveniently, via a 6 or 8 volt transformer from the A.C. mains. The temperature is controlled by a bimetallic thermostat and can be kept approximately constant anywhere in the range from 22 to 45°C. A small knob projecting from the chamber enables the temperature level to be altered at will. A small thermometer projects from the chamber so that the temperature can be watched by the observer. We have found that in general the temperature will remain constant within about ±1°C, but occasionally there may be slightly larger variations, though the observer can prevent these by adjusting the temperature-control knob.

The constancy of the temperature is accurate enough for ordinary microscopical work on living blood-cells—in fact, with this machine we have observed blood-cells under phase-contrast illumination in a healthy condition for at least six hours. The constancy of the temperature control is certainly much superior to that obtained with the ordinary microscope warm box, in which fluctuations of temperature are produced when the observer's hands are inserted from the sides.

(7) The warm stage was designed primarily for use with phase-contrast illumination. Previously we had used a warm box and had found it extremely difficult to control the various adjustments which have to be made so delicately in this type of illumination. All such difficulties are absent with the warm stage described, which in no way interferes with the controls of the microscope.

The warm stage has been made for us by Messrs. Kaylene Ltd., of Waterloo Road, Cricklewood, and we are very grateful to them for the trouble they have taken in perfecting the details of the design.

Reviews of Books

Malariology

Editor: MARK F. BOYD, M.D., M.S., M.P.H., formerly of field staff, International Health Division, Rockefeller Foundation; Director of the Station for Malaria Research, U.S.A. Philadelphia and London: W. B. Saunders. 1949. 2 vols. Pp. 1643. £8 15s.

IN 1930 Dr. Mark F. Boyd published his *Introduction to Malariology*, a modest volume of some 400 pages. Since that time, particularly under the stimulus of another war in the hyperendemic malarious areas of the world, advances have been great in our knowledge of malaria and its parasitology, of its insect vectors and the factors governing its incidence, of its prevention and control, and of its treatment, particularly with synthetic drugs. When Dr. Boyd wrote his original book the literature of malaria was already voluminous and polyglot, and it has since increased to the dimensions of a tower of Babel.

With the assistance of 64 authoritative collaborators of various nationalities, Dr. Boyd in these two volumes has once more collated modern knowledge of malaria. Recognised authorities from North, Central, and South America, from Britain and her Colonies, from the British Dominions, and from France and Russia contribute to an erudite, comprehensive, and catholic work. But even since this book went to the press English workers have demonstrated the existence of exoerythrocytic cycles of development of *Plasmodium vivax* and of *P. falciparum* in the human liver; so some sections of the book are already partly out of date, and others will soon require modification—as inevitably happens with any published work on a subject growing so rapidly. Most of the opinions expressed will be generally shared; but though, in the chapter headed Treatment of Patent Infections (that is, the treatment of clinical attacks of malaria), the statement may be acceptable that mepacrine by intramuscular injection is safe, effective, and the treatment of choice in grave cases of falciparum malaria, the assertions that there are no indications for the parenteral use of quinine, and that the intravenous use of this drug is attended by "a mortality of 33 per cent. in a preventable and a curable disease" are not in accord with the experience of the past half-century, during most of which there has been no alternative to quinine in the drug treatment of the malaria infections. This chapter is not as well documented as the rest, and the brief list of references is confined to recent work in the United States and personal communications. There is a substantial body of opinion that quinine, given intravenously, is still the best remedy when pernicious signs manifest themselves during the course of a malignant tertian malaria. Admittedly no drug so far has proved entirely satisfactory in the radical treatment of a malarial infection, and opinions must differ as to the virtues and manner of presentation of those available; but such sweeping condemnation of one of them without reference to wider experience is surprising in a work of this nature.

If there is room for differences of opinion there is also no doubt that this book is indispensable to all malariologists. And, though it is not primarily intended for the ordinary practitioner of medicine in the tropics, he will find it an invaluable source of reference.

Mr. Carlyle my Patient

JAMES L. HALLIDAY. London: Heinemann. 1949. Pp. 227. 15s.

ANY dyspeptic man of letters reading this book may well say of Dr. Halliday, as Arbuthnot said of Curll, that he has added another to the terrors of death: psycho-analysis-by-guesswork in this fashion would be a disagreeable post-mortem fate. Psychiatrists have often tried to diagnose the mental ills of the illustrious, their conjectures being of value in proportion to their clinical abilities and the amount of relevant information. Dr. Halliday, who, though an enthusiast for psycho-analysis, is not a psychiatrist, disclaims any attempt to explain Carlyle: he aims only to show that "when we study his life by psychosomatic and psychosocial approaches, certain relations are revealed which enable us to form concepts that are of practical significance." These relations—or these concepts—are mostly expressed by Dr. Halliday in anal metaphors, and those general readers who have never before learnt of the Freudian theory of stages of libidinal development will find this novel way of looking at Carlyle's personality and writings surprising as well as ingenious. The picture of Mr. Carlyle which emerges is not attractive, and we may assume that Dr. Halliday would have no difficulty in understanding Freud's remark, after he had written a study of Dostoievsky, that he did not really like the Russian author and that outside his clinical practice he was intolerant towards men of pathological nature. With a great deal that is suggestive and well written, Dr. Halliday mingles far-fetched guesses expressed in such language as "at last, on that warm afternoon in June, the ego made contact with the Terrible-Father complex. At this encounter, a flash of psychic energy from the complex passed over to the ego." In spite of passages like this, the book is a lively expansion and support of Leslie Stephen's opinion that Carlyle's letters and autobiographical writings "whether they attract or repel sympathy, are at least a series of documents of profound interest to any one who cares to study character"; though Dr. Halliday would probably deny the further statement that they "display an almost unique idiosyncrasy."

Advances in Food Research

Vol. II. Editors: E. M. MRAK, University of California; GEORGE F. STEWART, Iowa State College. New York. Academic Press. 1949. Pp. 558. $8.80.

THE recent report of the Medical Research Council for the years 1945–48 called attention to the increasing sophistication of food, and the appearance of this volume gives some idea of the way in which chemistry, engineering, and the most complicated industrial processes contribute to the preparation of the food that many of us eat without a thought for what has gone before. Who would have supposed for instance, that ingenious men had been using ion exchange resins to remove the bitter calcium malate from apple syrup?

There are nine articles in this volume. The one which deals with thermobacteriology as applied to food-processing is mathematical but reassuring. "During the past 20 years and more not a single case of botulism has been attributable to the consumption of commercially canned foods." This is good; and the article on the quarternary ammonium compounds, which seem to have a great future as disinfectants for containers and utensils, is interesting. So is the one on the spoilage of fish and its preservation by chilling; but the long final article on spray drying, excellent though it may be, is too technical for most people outside the industry. Some of the articles show that nature is not likely to yield up some of her secrets so easily as others. Man has still a lot to learn about the chemistry of fruit and vegetable flavours it seems; and it is difficult to grade or rate food by sensory tests. Yet the tea-tasters do it, and there are men who can forecast the quality of vintage port 25 years ahead. The volume also contains a short article on the pharmacology of D.D.T. and one on the histological changes induced by the processing of vegetables and fruits. Each article carries a considerable bibliography.

Truly this journal is a sign of the times: but are they altogether good times? Were we perhaps as well off eating weevils as we are with D.D.T., and is all that polyoxyethylene as good for us as it is for the taste of the bread to which it has been added? Time will tell. Meanwhile those who wish to be kept up to date about the technology and processing of food will probably find that the succeeding volumes of this journal will give them plenty of food—for thought.

An Outline of Psycho-analysis

SIGMUND FREUD. Authorised translation by James Strachey. London: Hogarth Press. 1949. Pp. 84. *8s. 6d.*

THIS last of Freud's writings is succinct, as its purpose requires: for he intended it as a concise dogmatic statement of the doctrines of psycho-analysis. In the introductory note he makes probably the most dogmatic statement of all: "the teachings of psycho-analysis are based upon an incalculable number of observations and experiences, and no one who has not repeated these observations upon himself or upon others is in a position to arrive at an independent judgment of it." This round assertion warning off any critical trespasser is a prelude to nine brief chapters, quite free from a take-it-or-leave-it harshness, couched in that style of explanation which Freud habitually adopted: he seemed to address always the friendly, not too prejudiced, listener eager to be instructed. The book is therefore neither dry nor bare, in spite of its brevity: and it combines authority with verbal simplicity in a way which lesser writers on psycho-analysis hardly ever attain.

Die Angstneurose: Entstehung und Heilung

W. BITTER, M.D., PH.D. Berne: Huber. 1948. Pp. 192. Sw. fr. 9.80.

Dr. Bitter holds that the theory and practice of divergent schools (such as those which originated with Freud and Jung) should be used fully, in accordance with the needs of individual patients. He illustrates this in a series of well-written chapters on the ætiology, psychopathology, and therapy of neurotic anxiety, which show a wide acquaintance with the relevant German literature. He seems, however, to have escaped the rigours of a formal training in psycho-analysis or in the individual psychology of Jung; he is therefore bold enough to describe in two detailed case-reports how he treated Miss E by analysis after the manner of Freud, and Mrs. C by analysis after the manner of Jung. Such virtuosity would hardly be possible in this country, where the analyst's allegiance sits closer and more exclusively on him. Dr. Bitter does not hold that elaborate psycho-analysis is needed for the bulk of patients with neurotic anxiety: briefer treatment, well within the competence of the beginner in psychotherapy, is efficacious with many of these, and his book is a plea for more extensive concern with the resolution of these patients' conflicts, by means of some of the simpler methods he describes.

Searchlights on Delinquency

New Psycho-analytic Studies. Dedicated to Prof. August Aichhorn on his 70th birthday. Editor: K. R. Eissler, M.D., PH.D. London: Imago Publishing Co. 1949. Pp. 456. *30s.*

Professor August Aichhorn wrote his book on Verwahrloste Jugend in 1925. In it he advocated methods of treating delinquency which were based on psycho-analysis and on his experience as a teacher and organiser of settlements for wayward neglected young people. His formulation of the libidinal structure of neurotic delinquents was accepted by psycho-analysts; it did not break new theoretical ground but enlarged the territory wherein analytic theory could be applied. Since then many analysts have concerned themselves with such problems. The 36 papers in this volume come from countries with different social organisations, but almost all are concerned mainly with the common endopsychic difficulties which lead to delinquent behaviour. One contributor, the medical historian Gregory Zilboorg, says that psycho-analysis has always looked upon society with suspicion and hostility, as the big reality which thwarts the individual's freedom and development: Zilboorg's discussion of this view, and of its implications in the psycho-analyst's attitude towards the criminal, raises some questions of urgency regarding the psychiatrist's—and indeed every doctor's—social responsibility. Among the other articles are two surveys, both coming from London, but amazingly discrepant in tone and emphasis: one is by Dorothy Archibald, on the services for London's difficult boys, and the other by Edward Glover, outlining the investigation and treatment of delinquency in Great Britain between 1912 and 1948. Other contributors in London include Anna Freud and the late Kate Friedlander.

Bennett's Materia Medica and Pharmacy (5th ed. London: H. K. Lewis & Co. 1950. Pp. 276. 16s.).—This was always a clear compact little book. It first appeared in 1908, and Mr. H. G. Rolfe, who has revised it, tells us in his preface that he has had the great help and encouragement of Mr. Reginald R. Bennett himself. What he does not tell us is the story behind the appearance, after a lapse of 29 years, of this new edition. Anyhow, here it is again, a small plump phœnix, packed with nourishment from the *British Pharmacopœia* of 1948.

Textbook of Physiology (originally by William H. Howell, M.D. 16th ed. Philadelphia and London: W. B. Saunders. 1949. Pp. 1258. £2 10s.).—Dr. John F. Fulton and his team of collaborators have produced a welcome new edition of this standard work. It is now the richer by a new long section on the endocrines by Dr. Jane Russell. The section on the electrocardiogram, always full, has been completely rewritten by Dr. Louis H. Nahum and Dr. H. M. Chernoff so as to include new work on unipolar E.C.G.s and to set out some general principles of interpretation. There are also new chapters on the gastro-intestinal tract, muscle, the cerebrospinal fluid, and the physiology of micturition. The rest of the work has been revised and pruned, to keep the balance true and the book wieldy.

Buchanan's Manual of Anatomy (8th ed. London: Baillière, Tindall, and Cox. 1949. Pp. 1616. 45s.).—The new edition has the same format and length as the last, and retains the original drawings by J. T. Murray which Prof. F. Wood Jones, F.R.S., as editor, restored to the seventh edition. It is true that these are, as he says, clear and beautiful as drawings; but some of the blocks are now getting so old and dark that careful study is needed to identify detail; and in fact the clearest drawings in the book are those which carry an unobtrusive W. J. in the corner. No colour is used, on principle; but perhaps those who find that colour helps them might spend a happy hour or two with coloured chalks: the paper is good enough to stand it, and there are worse ways of memorising structures.

Physiology in Health and Disease (5th ed. London: Henry Kimpton. 1949. Pp. 1242. 70s.).—In preparing this new edition of his work, Prof. Carl J. Wiggers, of Cleveland, has had the help of various members of his staff; so this highly individual work may have acquired, for students of Western Reserve University, something of a family flavour. His preface tells us that he has revised the text, in the sense of "again examining facts, statements, organisation of material, &c., with the idea of bringing them into conformity with new discoveries as well as with new viewpoints in correlative medical education. Mere patchwork upon the old does not constitute revision." With this aim in view he has included much new material on biophysics, and has revised the sections on subjects of such daily interest as pain, headache, paralysis, coagulation, coronary occlusion, and hypertension. He discusses experimental neurosis, and gives a chapter to the physiological basis of psychosomatic reactions which reminds the student vividly that organs which develop functional disorders are acting in response to messages sent from centres higher up and running along well-defined pathways. Thinking on these lines, the student is less likely to regard the psychosomatic disorders as an irritating piece of magic produced by patients to annoy their friends.

THE LANCET

LONDON: SATURDAY, MARCH 11, 1950

Physical Activity and Paralysis in Poliomyelitis

THE relation between physical activity and the subsequent development of paralysis in anterior poliomyelitis is of both practical and theoretical importance. There has been an impression for many years that severe paralysis may be precipitated by strenuous activity in the preparalytic stage of the disease, but RITCHIE RUSSELL[1] was the first to gather reliable evidence on this point. He studied 44 patients in the 1947 epidemic in England, obtaining detailed histories of their early symptoms and of their activities after the onset of symptoms and in the three days immediately preceding the onset. He found no correlation between physical activity in the three days before the onset and the degree of the subsequent paralysis, but he showed conclusively that physical activity during the 48 hours after the onset predisposed to severe paralysis, whereas patients who rested in bed from the start of their symptoms were unlikely to develop a disabling paralysis. Subsequently[2] he studied a further 56 cases from the same epidemic and confirmed his previous findings, and HARGREAVES,[3] after a comparable study of 30 patients, agreed with his conclusions.

In the United States, HORSTMANN[4] has investigated 411 cases of poliomyelitis in the 1948 epidemic on similar lines. About 20% of these patients had a prodromal stage of mild fever and constitutional symptoms lasting one or two days and then subsiding, to be succeeded three or four days later by a rise of temperature and symptoms of the meningitic phase of the disease. She found no significant difference in the amount of physical exercise taken in this prodromal phase between those who were eventually free from paralysis or only slightly paralysed and those who developed moderate or severe paralysis. But her findings were quite different when the meningitic stage was considered. Physical activity in the three days before the start of meningitic symptoms did not seem to affect the subsequent paralysis, but any physical exertion in the 48 hours after the onset undoubtedly made the patient more likely to develop moderate or severe paralysis. The incidence of paralysis was very much lower in those who rested in bed as soon as symptoms started: and of the patients who in fact developed moderate or severe paralysis, only 9% had stayed in bed or taken only minimal physical exercise during the 24 hours after the onset of symptoms, while 74% had continued with their normal activities. There were 64 cases of bulbar involvement in HORSTMANN's series, of which 9 were only mild; but in this group, in contrast to those with spinal involvement, no correlation was found between physical activity after the onset of symptoms and the subsequent disability.

Isolated case-histories sometimes suggest that individual muscles which are used excessively during the preparalytic phase are likely to be the site of subsequent paralysis, and in this issue (p. 460) a doctor who performed a difficult forceps delivery while he was in the early stage of poliomyelitis gives a good example of this. Usually, however, this possible association is difficult to establish or refute because of the complexity of most physical activities. HORSTMANN found that left-sided paralysis was rather commoner in the 28 left-handed patients in her series than in the 186 right-handed ones, but she could not produce any more detailed evidence.

The practical lesson to be learnt from RITCHIE RUSSELL and HORSTMANN's studies is that patients must be confined to bed at the beginning of the preparalytic phase. In sporadic cases, particularly in adults, this may be impossible. But in the poliomyelitis season the aim should be to keep in bed all children with mild febrile illnesses accompanied by headache and muscle pains. An energetic publicity campaign will be needed to convince parents and school teachers that complete rest is essential. On no account must anyone try to "work off" such symptoms. School sports and the like should so far as possible be held outside the poliomyelitis season. The theoretical implications are not so clear. It is generally agreed that during the preparalytic stage the virus is invading the central nervous system, and the susceptibility of the anterior horn cells to the attacks of the virus probably depends on various factors, including nutrition.[5] It has been shown[6] in experimental poliomyelitis in monkeys that exhausting exercise and chilling increase the incidence and severity of paralysis, and conversely[7] that division of a peripheral nerve a few days before infection will protect the anterior horn cells associated with that nerve from damage by the virus. Thus when the poliomyelitis virus has already invaded the nervous system, one factor which increases the chances of damage to anterior horn cells is physiological activity of those cells.

The Flow of Lymph

To us in the post-Harveian era it seems self-evident that the blood is pumped along by the rhythmically contracting heart. But for the lymph there is no obvious propelling mechanism in mammals. The frog is more fortunate, for it has two pairs of lymph hearts, and as a result of their activity the flow of lymph through the frog's lymphatic vessels in 24 hours may amount to fifty times its blood-volume.[8] [9] The generally accepted view is that the mammalian lymphatic system possesses no intrinsic pumping machinery and that the lymph is moved along by seems; and it is difficult to grade or rate food by sensory tests. Yet the tea-tasters do it, and there are men who can forecast the quality of vintage port 25 years ahead. The volume also contains a short article on the pharmacology of D.D.T. and one on the histological changes induced by the processing of vegetables and fruits. Each article carries a considerable bibliography.

Meanwhile those who wish to be kept up to date about the technology and processing of food will probably find that the succeeding volumes of this journal will give them plenty of food—for thought.

An Outline of Psycho-analysis

SIGMUND FREUD. Authorised translation by James Strachey. London: Hogarth Press. 1949. Pp. 84. 8*s.* 6*d.*

THIS last of Freud's writings is succinct, as its purpose requires: for he intended it as a concise dogmatic statement of the doctrines of psycho-analysis. In the introductory note he makes probably the most dogmatic statement of all: "the teachings of psycho-analysis are based upon an incalculable number of observations and experiences, and no one who has not repeated these observations upon himself or upon others is in a position to arrive at an independent judgment of it." This round assertion warning off any critical trespasser is a prelude to nine brief chapters, quite free from a take-it-or-leave-it harshness, couched in that style of explanation which Freud habitually adopted: he seemed to address always the friendly, not too prejudiced, listener eager to be instructed. The book is therefore neither dry nor bare, in spite of its brevity: and it combines authority with verbal simplicity in a way which lesser writers on psycho-analysis hardly ever attain.

Die Angstneurose: Entstehung und Heilung

W. BITTER, M.D., PH.D. Berne: Huber. 1948. Pp. 192. Sw. fr. 9.80.

Dr. Bitter holds that the theory and practice of divergent schools (such as those which originated with Freud and Jung) should be used fully, in accordance with the needs of individual patients. He illustrates this in a series of well-written chapters on the ætiology, psychopathology, and therapy of neurotic anxiety, which show a wide acquaintance with the relevant German literature. He seems, however, to have escaped the rigours of a formal training in psycho-analysis or in the individual psychology of Jung; he is therefore bold enough to describe in two detailed case-reports how he treated Miss E by analysis after the manner of Freud, and Mrs. C by analysis after the manner of Jung. Such virtuosity would hardly be possible in this country, where the analyst's allegiance sits closer and more exclusively on him. Dr. Bitter does not hold that elaborate psycho-analysis is needed for the bulk of patients with neurotic anxiety: briefer treatment, well within the competence of the beginner in psychotherapy, is efficacious with many of these, and his book is a plea for more extensive concern with the resolution of these patients' conflicts, by means of some of the simpler methods he describes.

Searchlights on Delinquency

New Psycho-analytic Studies. Dedicated to Prof. August Aichhorn on his 70th birthday. Editor: K. R. Eissler, M.D., PH.D. London: Imago Publishing Co. 1949. Pp. 456. 30*s.*

Professor August Aichhorn wrote his book on Verwahrloste Jugend in 1925. In it he advocated methods of treating delinquency which were based on psycho-analysis and on his experience as a teacher and organiser of settlements for wayward neglected young people. His formulation of the libidinal structure of neurotic delinquents was accepted by psycho-analysts; it did not break new theoretical ground but enlarged the territory wherein analytic theory could be applied. Since then many analysts have concerned themselves with such problems. The 36 papers in this volume come from countries with different social organisations, but almost all are concerned mainly with the common endopsychic difficulties which lead to delinquent behaviour. One contributor, the medical historian Gregory Zilboorg, says that psycho-analysis has always looked upon society with suspicion and hostility, as the big reality which thwarts the individual's freedom and development: Zilboorg's discussion of this view, and of its implications in the psycho-analyst's attitude towards the criminal, raises some questions of urgency regarding the psychiatrist's—and indeed every doctor's—social responsibility. Among the other articles are two surveys, both coming from London, but amazingly discrepant in tone and emphasis: one is by Dorothy Archibald, on the services for London's difficult boys, and the other by Edward Glover, outlining the investigation and treatment of delinquency in Great Britain between 1912 and 1948. Other contributors in London include Anna Freud and the late Kate Friedlander.

Bennett's Materia Medica and Pharmacy (5th ed. London: H. K. Lewis & Co. 1950. Pp. 276. 16*s.*).—This was always a clear compact little book. It first appeared in 1908, and Mr. H. G. Rolfe, who has revised it, tells us in his preface that he has had the great help and encouragement of Mr. Reginald R. Bennett himself. What he does not tell us is the story behind the appearance, after a lapse of 29 years, of this new edition. Anyhow, here it is again, a small plump phœnix, packed with nourishment from the *British Pharmacopœia* of 1948.

Textbook of Physiology (originally by William H. Howell, M.D. 16th ed. Philadelphia and London: W. B. Saunders. 1949. Pp. 1258. £2 10*s.*).—Dr. John F. Fulton and his team of collaborators have produced a welcome new edition of this standard work. It is now the richer by a new long section on the endocrines by Dr. Jane Russell. The section on the electrocardiogram, always full, has been completely rewritten by Dr. Louis H. Nahum and Dr. H. M. Chernoff so as to include new work on unipolar E.C.G.s and to set out some general principles of interpretation. There are also new chapters on the gastro-intestinal tract, muscle, the cerebrospinal fluid, and the physiology of micturition. The rest of the work has been revised and pruned, to keep the balance true and the book wieldy.

Buchanan's Manual of Anatomy (8th ed. London: Baillière, Tindall, and Cox. 1949. Pp. 1616. 45*s.*).—The new edition has the same format and length as the last, and retains the original drawings by J. T. Murray which Prof. F. Wood Jones, F.R.S., as editor, restored to the seventh edition. It is true that these are, as he says, clear and beautiful as drawings; but some of the blocks are now getting so old and dark that careful study is needed to identify detail; and in fact the clearest drawings in the book are those which carry an unobtrusive W. J. in the corner. No colour is used, on principle; but perhaps those who find that colour helps them might spend a happy hour or two with coloured chalks: the paper is good enough to stand it, and there are worse ways of memorising structures.

Physiology in Health and Disease (5th ed. London: Henry Kimpton. 1949. Pp. 1242. 70*s.*).—In preparing this new edition of his work, Prof. Carl J. Wiggers, of Cleveland, has had the help of various members of his staff; so this highly individual work may have acquired, for students of Western Reserve University, something of a family flavour. His preface tells us that he has revised the text, in the sense of "again examining facts, statements, organisation of material, &c., with the idea of bringing them into conformity with new discoveries as well as with new viewpoints in correlative medical education. Mere patchwork upon the old does not constitute revision." With this aim in view he has included much new material on biophysics, and has revised the sections on subjects of such daily interest as pain, headache, paralysis, coagulation, coronary occlusion, and hypertension. He discusses experimental neurosis, and gives a chapter to the physiological basis of psychosomatic reactions which reminds the student vividly that organs which develop functional disorders are acting in response to messages sent from centres higher up and running along well-defined pathways. Thinking on these lines, the student is less likely to regard the psychosomatic disorders as an irritating piece of magic produced by patients to annoy their friends.

the propulsion of mammalian lymph. However, where intrinsic contractility of peripheral lymphatics does exist, how is the mechanism controlled? SMITH could not demonstrate any clear-cut effect on the lymph vessels and lymph-flow after either section or stimulation of the femoral and sciatic nerves, though local application of adrenaline or pituitary extract produced definite contraction. His experiments throw no light on the problem which often confronts investigators—the occasional complete "dryness" of a region from whose lymphatics there is usually a fair flow of lymph. But localised spasm of contractile vessels is clearly a possible explanation.

Morbidity in Infancy

THE latest of the social-medicine reports from Luton raises a number of important issues. *Illness in Infancy*[1] is a study by Dr. R. M. DYKES, the medical officer of health, of infant morbidity in this industrial town of 110,000 inhabitants. It is concerned with the infants born there in 1945 who could be observed throughout their first year; these numbered 1498, comprising 79% of the total births.

Disease incidents were established by one of the following criteria: (*a*) confinement to bed for at least 48 hours; (*b*) the calling of a doctor; (*c*) the production of a recognised disability. Among the 1498 infants, there were 564 disease incidents during the first year of life—an average of 1 incident for every 2·6 infants—and more than half of the incidents were concentrated in less than 7% of the infants. Nearly half of the illnesses were respiratory; gastro-enteritis and whooping-cough each accounted for 11%, and measles for 7%; accidents, including burns, accounted for only 1%. The proportionate distribution of the causes of first and second illnesses did not differ greatly. The social class of the father had no significant influence on the morbidity-rate or on the duration of illness. The general belief that the larger the family the higher the incidence of disease in the youngest member during infancy was confirmed; but the advantage enjoyed in the first year by the only child over the youngest of several was only small. In Luton, with its comparatively favourable social conditions, the standard of housing had no important effect on the incidence of illness. The breast-feeding history was illuminating: the age of weaning was independent of family size, social class, and housing standard; and with the notable exception of gastro-enteritis the age of weaning was the same in infants who fell ill as in those who remained well. In those who developed gastro-enteritis weaning took place particularly early.

Of the whole group 90 (7%) with the worst sickness records had an average of 63 days of illness. These were compared with an equal number of infants who had not suffered any illness. The two groups were reasonably well matched for social class, family size, maternal age, incidence of prematurity, birth weight, breast-feeding history, and room-population density. Thus attention came to be centred on constitutional factors and the standard of infant care. Assessment by health visitors showed that the standard of care was similar in the two groups; and since the standard varied directly with the social class, whereas the incidence of morbidity did not, this could not have been important in determining morbidity. While acknowledging that it is "scientifically foolhardy" to attribute the difference to constitutional factors simply because other causes have been excluded, DYKES sees no alternative; and he suggests that the constitutional theory is supported by the disproportionately large number of respiratory and skin diseases in the high-incidence group—a view to which most clinicians would subscribe.

Luton is a prosperous industrial town in south-east England, enjoying a better climate than much of the British Isles; and rightly the report emphasises that Luton's experience may not reflect the experience of other towns or of rural areas. In Luton, which has no social morbidity-gradient, infant morbidity would apparently not be reduced by raising the standard of living of the less well-to-do sections of the community. In cities with congested slums this would almost certainly not hold true. Happily, a few similar studies are being conducted elsewhere in the country, and it will be of great value to compare the results. Clearly, in places with a social morbidity-gradient, if the circumstances of the less favoured groups could be raised to the level prevailing in the prosperous town of Luton, infant morbidity would be reduced. There may be a social level (perhaps already attained in Luton) beyond which further social improvement would have little or no effect on morbidity.

In Luton, as elsewhere, the infant-mortality rate varies with the social class; during the three years 1945–47 the rate was 31 per 1000 legitimate live births in classes I–III, compared with 52 in classes IV and V. This demonstration of a mortality gradient where there is no morbidity gradient confirms the value of the infant-mortality rate as an index of standards of living in the widest sense. It shows that differences between the social classes, which appear to be without effect on morbidity incidence, play a material part in determining the risk of death. There are two possible explanations: either infants in poorer circumstances have a relatively lower resistance to established disease, or else the sick infant needs, for the best chance of recovery, a standard of care which is given in some social groups and not in others. The first of these possibilities is unlikely; the second is much more acceptable, for it is supported by the causes of death. In the 1945 group 36% of the deaths were caused by respiratory and gastro-intestinal infections, many of them regarded as preventable; and in the lower-income groups medical aid was less often obtained than in the higher-income groups. Desire to avoid expense was, it seems, a more important reason for this than less well-developed parental solicitude or judgment: and a possible implication is that the National Health Service, which gives everyone the right to obtain medical assistance without charge, may contribute to a further fall in mortality. In fact the sharp fall in 1949 may be partly explained in this way. The vital rôle of a highly organised and efficient health service in reducing infant mortality has been amply demonstrated in Chicago.

[1] Illness in Infancy: A Comparative Study of Infant Sickness and Infant Mortality in Luton. By R. M. Dykes, M.D., D.P.H., medical officer of health, Luton: with a foreword by Prof. Fred Grundy, M.D. Published by the Health Department, Town Hall, Luton. Pp. 46. 3*s*. 6*d*.

forces outside the system.[10] The extrinsic forces are effective because of the many valves present in all except the smallest lymph vessels. In thin-walled lymphatics distended with lymph these closely placed valves give rise to a characteristic beaded appearance, and they are a frequent source of trouble in experiments involving lymphatic cannulation. Valves are not found in the lymphatic vessels of fishes, amphibia, or reptiles; they make their first appearance in mammals, concurrently with the extensive development of lymph-glands.

Once valves have developed, any form of extrinsic pressure on the vessels, whether active or passive, will propel the lymph along. Thus, in an anæsthetised dog, if a cannula is inserted into one of the medium-sized collecting trunks near the ankle there is no spontaneous flow of lymph. But if the pad of the foot is squeezed and the foot is massaged a steady flow of lymph usually begins. A similar flow occurs if the animal is allowed to recover from the anæsthetic and then walk or run about.[11] These simple experiments illustrate one of the main ways in which complete immobilisation of inflamed limbs is beneficial: it reduces lymph-flow, and the consequent spread of bacteria along lymphatics, to a minimum. As would be expected if muscular contraction produces lymph movement, the lymph-trunks draining the heart always show a steady flow. The heart is in fact a particularly favourable organ for the study of lymph-flow, because all the lymph leaving it can be collected; and it can readily be shown that if the work of the heart is increased—e.g., with adrenaline—there is a corresponding increase in the flow of lymph. The intestine provides another example of the action of extrinsic pressure. Peristalsis stimulates lymph-flow by compressing the intestinal contents against the mucous membrane, with its rich lymphatic network; and where villi are present their movement has the same effect. The propulsion of lymph by peristalsis has been directly observed in the mouse by Florey [12]: "Each movement was observed to compress the lacteals contained in the gut wall, and as these are furnished with valves the contained fluid was forced along." For the intestine as a whole, this effect of peristalsis can be observed by cannulating the thoracic duct. In the anæsthetised dog there is usually a spontaneous flow of lymph from the thoracic duct, amounting to about 2·4 ml. per kg. of body-weight every hour.[13] Most of this lymph is derived from the intestine, and an injection of pilocarpine, which causes contraction of the intestinal musculature will greatly increase the flow.[14] The pulsation of adjacent blood-vessels has also been invoked as an important extrinsic factor in promoting lymph-flow. Parsons and McMaster [15] perfused the blood-vessels of a rabbit's ear with defibrinated blood, and found that if the pressure became pulsatile there was an active flow of lymph. Cressman and Blalock [16] suggested that pulsation of the abdominal aorta might exert an important action on the adjacent *receptaculum chyli*. However, it is difficult to believe that vascular pulsation plays a large part in normal lymph movement, for cannulation of the main limb lymphatics hardly ever reveals any flow unless the limb is massaged or moved about. In the dog and cat, the same applies to the deep cervical trunk which drains the head and neck, and this is especially significant since it is closely related to the common carotid artery. McCarrell [17] devised an apparatus for producing continued passive movement of the head in anæsthetised dogs, and thereby obtained a steady flow of lymph through the deep cervical trunk. Normally the effect of head and neck movements is no doubt supplemented by the muscular activity of swallowing and the compression of submucous lymphatics by the bolus of food. Moreover, the cerebrospinal fluid may exert an additional vis a tergo. The pressure in the cerebrospinal fluid is some four times that in the deep cervical lymph-trunk, and by the injection of indian-ink particles into the cisterna magna at physiological pressures it has been shown [18] that cerebrospinal fluid can pass readily out of the cranium, along the perineural spaces of the cranial nerves, and so reach the cervical lymphatics. This may have a significant effect on lymph-flow in animals with a relatively large volume of cerebrospinal fluid; and may explain why in the monkey, though the cervical trunk is a much finer vessel than in the cat or dog, cannulation usually produces a steady and spontaneous flow of lymph.[19]

Despite all these extrinsic factors—and others such as diaphragmatic and abdominal wall movements, and pressure changes in the thorax during respiration—there is still occasional evidence of a partial intrinsic mechanism in mammals. There is a certain amount of smooth muscle in the walls of most lymphatic vessels, and muscle has also been described in the capsules of lymph-glands in some species. Rhythmical contraction and relaxation of the smooth muscle of lymphatic vessels may to a varying extent take the place of the lymph hearts of lower vertebrates. The classical papers of Florey and his co-workers [20] contain extensive studies of the properties of lymphatic vessels in a variety of animals. The most favourable site for demonstrating rhythmical contraction seems to be the mesenteric lacteals, and here they observed peristaltic contraction in the guineapig and rat, but not in the cat, dog, squirrel, hedgehog, mouse, pig, or man. They also described contraction of lymph vessels in the thigh, spermatic cord, and diaphragm, and similar observations have been made on the lymph vessels of the bat's wing.[21] Smith,[22] who has lately studied the flow in the afferent and efferent vessels of the popliteal lymph-gland, finds lymphatic contractility in rats, mice, and guineapigs, but none in rabbits or dogs. The fact that such contractility can be readily observed in some animals but not in others suggests that it is not an essential element in

or the bus queue. Many foreigners coming to this country during and before the war had no such experience behind them; they had rather learnt that to get served at all they must use subterfuge and guile. They really did not believe that if they waited their turn they would get exactly the same as everyone else—no more and no less—of whatever was going. Their queue manners were therefore bad and roused the sharpest antagonism. They learned in time that their fears were groundless: but by that time they had innocently done great harm to their own cause. No initial ill-will is responsible for such clashes of different experience. They are perhaps unavoidable in the sense that we shall be incapable of avoiding them until children are taught, from their earliest years, to look for the reason behind the stranger's strange behaviour, and to withhold judgment in the meantime.

THE IDEAL MEDICAL FILM

Having accepted that the film has a place in medical education, there remain the questions, What place? and What films? At a meeting of the Scientific Film Association in London last month there was agreement that the medical film must be designed with a specific audience in view and that there is a distinct place for the very short film teaching a special technique, or illustrating a process that normally takes a long time or is rarely seen.

At last month's meeting Prof. R. J. S. McDowall was supported by other speakers when he suggested that most medical films are too long; captions should also be short and each new point should be talked about or captioned. These films may be divided broadly into those for premedical, for clinical, and for postgraduate students, those made for recording purposes, and those for education of the public. Among special uses of films in medical education mentioned by Professor McDowall were the demonstration to second-year and third-year students of what goes on in hospital and to senior clinical students of laboratory procedure. Prof. Robert Cruickshank said that in teaching bacteriology he employed films to show the social background. as well as to introduce discussion on a particular subject (for example, inflammation) and to show techniques (such as gram-staining). Mr. C. J. Longland spoke of the value of films in illustrating the developing picture of disease—in acute appendicitis, for instance. As to subjects, Professor McDowall held that films should not replace what the student could see for himself but should show something which otherwise would not be seen; and he gave as examples the movement of villi of the intestine (which had not been believed until it was filmed) and large-scale subjects such as the preparation of penicillin. Other suggestions were for films of isolated clinical signs, where it might not be easy to show a case when wanted, and of single techniques, and for "snippets"—extracts of films to illustrate one point in a lecture after the manner of an animated lantern-slide.

Who should produce a medical film? The need is for doctors who have mastered the mechanics of film-making. Dr. R. G. W. Ollerenshaw remarked that such doubly qualified men are few. and their services should not be misused—in particular, senior medical men should not take umbrage if the school unit turned down their idea. He thought that if the ideal medical film were ever made, it would be by a medical school and its own unit; nevertheless there would always be a place for highly specialised technical assistance. There must be very careful preparation of films, which should not be undertaken merely for prestige purposes; and there should be full coöperation and consultation, including criticism by other teachers. Use should also be made of the Scientific Film Association's advisory service, to avoid unnecessary duplication. In the actual making of the film, recourse should be had to all technical devices—fading and mixing, for example, to avoid showing all the stitching of an incision, and animated-diagrams, because the essential of a film was movement and where, as in a diagram. there was no inherent movement, it must be imparted. Professor McDowall made a plea for the appearance of film publishers, on the lines of book publishers. It was also suggested that the University Grants Committee should contribute to the high cost of medical teaching films.

Although medical films have long been in use—it was in 1897 that Macintyre, of Glasgow, made the first animated X-ray film to show movement of the joints—little is known of audience reaction. Sir Kenneth Goadby, who presided at last month's meeting, called for further observations in this field. Professor McDowall had been horrified to find, when he set an examination question on a film, how little had been learned. Here the question of colour versus black-and-white may be relevant. Some work by Rosenthal,[1] in Melbourne, suggests that while colour gives a more vivid impression for a day or two, the long-term effect of black-and-white may be greater; on the other hand, many feel that colour, being more realistic, is clearer. Bound up with assimilation of content is facility for note-taking. Provided that the illumination on the screen is good, sufficient house-lighting can be retained for rough notes to be made during the showing: but it is clearly best not to take notes under these conditions, while the film presses on its relentless way. There is much to be said for providing a duplicated précis or for projecting on the screen notes to be copied; and another suggestion was that ten minutes of film should be followed by a period for note-making. Then again, the student will often benefit by seeing the same film more than once; he would not expect to assimilate a chapter in a textbook of physiology by reading it once, and it may be if anything rather more difficult to grasp the visual impression of a film, which goes its own pace.

While there are a number of extremely good medical films, there are many which are not so good. The aim should be to succeed where the commercial cinema has failed—to keep the proportion of "not so goods" within bounds.

ODD FEET

Careful of the fit of our clothes and our teeth, we are yet willing—especially the women among us—to accept for our feet the standardised products of a creative and fanciful industry. For women, height of heel or width of toe may vary extravagantly in the course of a season or so; and to every change the bones and ligaments of the foot perforce adjust themselves, paddling through life as humble and gallant as coolies pulling a rickshaw. Only when the years have added their increment to the load does the owner condescend to pamper her feet with the easy heel and the broad toe.

But there is one class of people who cannot afford to drive their feet so hard. and yet who find it peculiarly difficult to get shod. These are they who, for one reason or another, have feet of different sizes. The discrepancy may be due to congenital deformity, old poliomyelitis, or failure of one foot to grow after some injury or operation or because of some trophic disturbance. Whatever the cause, the patient may be quite capable of wearing an ordinary shoe on either foot, but the shoes must differ from each other by as much as one or two sizes or more. The trouble. expense, and annoyance this can cause is considerable. At first glance the solution seems to be to have shoes made; but shoemakers are traditionally obstinate, and it is exceedingly difficult to get them to make anything but a stout

"THE FLU"

DOCTORS in general practice the world over are continually having to deal with transient fevers at all seasons, yet except during an epidemic it is seldom practicable to make a precise diagnosis. At the meeting of the section of medicine of the Royal Society of Medicine on Feb. 28, under the chairmanship of Sir Adolphe Abrahams, Dr. C. H. Andrewes, F.R.S., and Prof. C. H. Stuart-Harris dealt with the laboratory and clinical aspects of these fevers and Dr. C. J. Gavey outlined the clinical problem they present in hot countries. Laboratory investigation can sometimes help to separate off influenza A and B by mouse-inoculation tests, atypical pneumonia by cold-agglutinin tests, and Q fever by complement-fixation tests, but in the individual patient in practice it is virtually impossible to differentiate these from febrile catarrhs, the common cold, and other respiratory infections labelled according to their main anatomical sites, such as laryngitis or tracheobronchitis. Occasionally, enlarged glands or a routine inspection of a blood film will reveal the atypical case of glandular fever. But there remain a host of short fevers with no local or general distinguishing features which are really infections like poliomyelitis, infective hepatitis, or choriomeningitis rendered abortive by the low virulence of the organisms or the patient's high immunity.

Upper respiratory infections of uncertain origin and true influenza account for the majority of short fevers in this country. Most of these entail three days' and the remainder seven days' incapacity. A longer illness is a strong indication for a diligent search for evidences of major diseases such as pneumonia, tuberculosis, undulant fever, urinary infections, or rarer conditions such as infective endocarditis or the leukæmias. The studies made among nurses and factory workers illustrate the importance of respiratory infections, which account for about a third of all the working days lost through illness. Short fevers with diarrhœa should not be called influenza, because Sonne dysentery is usually responsible for them. Vomiting may occasionally be seen in true influenza, but the view of this meeting was that most infections labelled "gastric flu" prove not to be influenza when investigated by laboratory methods but are due to a separate virus. Further study of short fevers is hampered by the difficulty in culturing the various viruses concerned, and by the need for transmission to animals for identification. Moreover, the various clinical features are compressed into a few days and the clinical picture may alter in a few hours. Chronic respiratory catarrh is widespread and any fever tends to aggravate it, thus overshadowing the more characteristic symptoms. The most fruitful study is likely to be on the lines of the Salisbury experiment on volunteers, but such studies are limited by the scarcity of suitable volunteers, especially for the more unpleasant infections. Tropical short fevers are even more difficult to study because the range is made much wider by the inclusion of abortive attacks of endemic diseases such as malaria, amœbic and bacillary dysentery, typhoid, typhus, relapsing fever, and bilharziasis. Malaria is usually proved easily by blood smears but some cases defy diagnosis and so must be included among the short fevers. The incidences of these short fevers and of malaria are roughly equal. Closely following them in incidence are the upper respiratory infections which have much the same features as in this country.

What of treatment? Antibiotics such as 'Aureomycin' have an anti-virus action but are not yet available for minor maladies. Indeed it is questionable whether powerful drugs should be exhibited in short fevers, since they do harm as often as they do good, by obviating nature's demand for rest, though antibiotics may be of crucial value in old people. Vaccination against influenza is disappointing because the immunity so obtained is transient, probably lasting only two months. Should the sufferers from the common cold be isolated? Work at Salisbury has shown that volunteers become infectious 24 hours before the ordinary manifestations appear. It is perhaps desirable for school-children to be isolated but isolation is not practicable in industry.

ANTAGONISM TO STRANGERS

THE last time our islands had a big influx of strangers was in 1066. The war has brought a more peaceable but quite large invasion, and has made us, as Prof. W. J. Rose suggested to the Institute of Sociology on Feb. 28, almost as much of a melting-pot as the New World. He quoted the view of Gorer that the British have shown xenophobia for years. Strangeness implies the existence of *nostri et alieni*; but what are the qualities of "otherness" which rouse antagonism towards *alieni*? Superficially they are mainly differences in appearance or behaviour—feeding differences, differences of speech, dress, colour, or occupation (the caste system in India still rests on differences of occupation). But Professor Rose endorsed Zanietski's view, expressed thirty years ago, that these differences are not in themselves causes of antagonism. In other words, antagonism is not inherent in the facts of the situation. This is clear enough from the readiness with which American white children accept their coloured companions at school—up to a certain age. They feel no inherent antagonism about colour: they acquire it later. When a mob acts in concert, he said, its members are ashamed next morning, and feel a sense of strangeness and antagonism to those with whom they had been in accord the night before. Strangeness, then, is a purely subjective thing; and "strangers," to a given individual or horde, are only those who are experienced as such at the time. Unless there is contact of some sort—even contact at a distance—there can be no antagonism. The stranger always appears as an intruder on our thoughts or designs or activities.

In the discussion which followed, some spoke of the mechanism of unconscious projection, by which we foist on to others the qualities we have repressed—as too bad to be borne—in ourselves. We are thus able to endow strangers with attributes which we can conscientiously dislike. The word scapegoat was not specifically used, but examples were ready to hand of cases where the stranger, or the stranger race, has been made to bear the blame on behalf of the rest of the community. An even commoner mechanism was not mentioned—that by which we endow the stranger with powers of intellect or capacity for success far beyond our own, and resent him accordingly; from there it is but a step in simple projection to credit him with ill-will or even malice towards ourselves. The subtle and malevolent stranger is a most dismaying concept—father of all the mysterious Chinamen, clever anarchists, and mad professors of adolescent literature.

These various explanations may throw some useful light on British xenophobia. Certainly we are apt to suspect foreigners of being a bit too clever, partly because they learn to talk our language so quickly, so fluently, and so much. But this after all is a convenience to us, and should be valued accordingly. Differences of custom or behaviour may not be inherently causes of dislike, but it must be remembered that some customs are associated with strong traditional emotions. The infringement of these by some counter-custom is indeed an invasion, and will at once be interpreted as an aggressive act. Thus the British public are well conditioned to the ethics of queueing; we resent keenly the behaviour of anyone, British or not, who tries to get ahead of his turn, whether in the grocer's, the doctor's waiting-room,

Points of View

WAR

ITS ORIGIN IN THE MINDS OF MEN

RANYARD WEST

M.D. Lond., D.Phil. Oxfd, M.R.C.P.

(Concluded from p. 416)

III. Universal War versus Positive Law

THE suggestion that wars arise in the minds of ordinary men just because they are men is hardly surprising when we consider the almost universal disposition to warfare shown by the human race. When we hear of very primitive aborigines who do not resort to war habitually, we are inclined to ask what is wrong with them, or whether they were not, perhaps, on their very best behaviour for Mr. Malinowski's visit. Because, until "positive law" was pragmatically discovered and introduced, there was no solution to any serious quarrel except by fighting about it. Given the quarrel, the fight followed—though the fight might be no more than a threat, or result perhaps in a "moral" victory.

Some men, of course, have learnt to avoid—often with wonderful skill—the personal quarrels which they know will gall their lives and ruin their happiness. But only some men can do that; and it is improbable that any of us could be trusted to conduct ourselves through a wholly peaceable lifetime in the total absence of external restraint.

It so happens that none of us is called upon to try. When a man avoids a given quarrel today he does so under many restraining influences. Let him pursue his quarrel to an open broil and he will hardly find that society awards him high marks for virtue. He is not free and primitive but a socially trained animal. The most selfish and ruthless of men still operates within a rigid framework of control by external and internal "sanction."

The three-year-old has already made most of the essential discoveries. Susan Isaacs found that the only reason why her nursery children accepted justice from grown-ups was their fear of losing the fight with each other. Similarly, to get as nearly as possible what we think we want, without the risks of mortal combat, is the idea underlying all litigation. And to get as much as we can allow ourselves to want, without incurring the expense of litigation, or the stigma of arraignment, or the penalties of social ostracism, has long been established as the aim of civilised man.

PSYCHOLOGICAL RÔLE OF LAW IN HUMAN ORDER

Long ago, in a thousand different situations of tribe and race, the more able and ambitious among men must at some time have begun to note the following points:

(1) If you want people to work for you, you must stop them fighting among themselves.

(2) The obvious way to stop them fighting is by force.

(3) A great economy of force can be exercised by checking outbreaks of violence before they occur.

This last the wise ruler proceeded to do in two ways. First he paraded his forces: a large foreman with a whip, sentries with guns, and a policeman with a telephone are all in the same straight line here. Next he provided alternative means of settling disputes. The method was that of the modern nursery: "Bring it to me (or take it to Nanny!") and we'll tell you whose it is."

The sort of justice dispensed by primitive man varied: much of it must have been rough. Apparently the Greeks sought absolute justice—for a few. The Romans, pressed upon by the necessities of empire and by common sense, sought primarily a solution—for everyone. Right on throughout the medieval world "justice" had to be provided, not between ruler and subject but between subject and subject for the peace and welfare of the ruler. But in the end the blessings of law came to benefit its subjects more than their tyrants. Judiciously combined with force, it has in most places enabled them to overthrow their overlords, setting up much new legal machinery and many new rules but also taking over much of both from their one-time masters. Thus has mankind come by what is probably the greatest defensive weapon of civilisation—the rule of positive law administered impartially enough for the common man to applaud its rulings in general and therefore to accept, however reluctantly, its ruling in his own particular case.

INEVITABLE PREJUDICE

It has often been said that litigation should be made easier. In many cases it might well be made cheaper. But possibly it is a sign of normal health in a modern community that most of us will go a long way to avoid litigation, cheap or dear. Why? The problem of a house, a rent, damages for trespass, neglect, failure to exercise due care and attention—whatever it be—who among us faces legal action with sang-froid? Why do we get hot and bothered about any case of ours coming into the courts? Is it not because our case may be "misunderstood"? Our solicitor does not find it quite so strong legally as we know it to be morally. It becomes a bit of a gamble, a gamble we fondly think between the truth of the facts and the folly of the law.

Actually, however, the law is not inclined to folly or easily misled. After a long history and many approximations it does now seek to preserve a proper balance between rights and obligations, to secure peace, and to do justice; and under normal conditions it does them all very well. Actually, therefore, in our particular case, in our own little brush with the law, the issue is not, as we suppose, between the truth we know and the law's capacity to err, but between our prejudice and the truth as it is discoverable by the skilled application of the long experience of a legal rule. A chief function of the law is to correct our prejudicial judgment applied to facts. The law of the land has gained our support because we believe ourselves to be inevitably on the side of the angels: that which protects the "good" man protects us. But the task of the law, in civil and in criminal cases alike, is to correct the inevitable prejudices of the parties and discover a just verdict somehow between or amongst them. In civil cases (and in many criminal cases too) it is a matter of holding up a mirror of established principle, and well-grounded public opinion, before the face of a man who has hitherto been good in his own eyes. So good that, given ordinary courage and a sporting chance, he is ready to fight another good man for his rights.

RESPONSE, EXPERIENCE, AND JUDGMENT

How do we come by the prejudices that make us judge our own cause with partiality and fight for our own hand whenever the blessed restraint of law is absent? The answer comes from a glance back at the way the human person attains experience of the world in which he lives.

Experience comes to him from bodily contact and sensory stimuli—the afferent side of an appropriate reflex. But the main object of the reflex is an appropriate motor response. If the infant is about to fall on its head, its hand goes out to protect it. If the fall is sufficient or the hands don't go out quickly enough, that may be the end of the story for that particular infant. If the hands go out successfully, one of many defensive pathways is established, and repetitions will quicken and improve the response. Whether the infant can then be said to be "remembering" the desirability of protecting its head with its hands is not very important: that it shall "understand" the physical principles involved in its action is totally unimportant.

reliable shoe of exquisite workmanship, weighing about as much as the iron shoes of the fairy tales. This is all very well for the larger foot of the two, but the smaller foot is often—for one reason or another—weak and tender. It is not fit to lug a great walking shoe about: it needs something as soft, light, and pliable as a ballet-dancer's boot. Yet it is quite impossible, it seems, for the ordinary person to get such footgear made. Theatrical shoemakers are off-hand with customers not in the profession; and to the hand-maker of shoes the whole notion seems to be repugnant.

The other solution at present open to the person with odd feet is to go into an ordinary shop, buy two pairs of shoes, and discard the two shoes he cannot wear. This expensive and wasteful practice could be avoided with a little help from the trade. Before the war some firms were willing to take back the two odd shoes and send them to the factory to be paired up. They charged the buyer the price of a single pair of shoes plus a small fee—half a crown or so—for the trouble entailed. This arrangement was very reasonable, and might well be revived by the more progressive firms today. The number of people who would be benefited, though not large, is probably greater than is generally supposed.

It would be even better, of course, if some hand-makers of shoes would specialise in light-weight pliable footgear—not only for cases of this kind, but for paraplegics and others with motor disorders of the legs and feet. Heavy shoes are so fatiguing to the partially paralysed limb that some patients—even on their walks abroad—discard their beautifully finished surgical boots and shoes in favour of bedroom slippers, which give them no support of any kind. In their view the value to be derived from springs, callipers, and suchlike gear, is completely offset by the weight of the whole contrivance, and particularly of the shoes. Surgical bootmakers might think this over.

THE ART AND SCIENCE OF WASHING-UP

THE campaign for cleaner food has led to a close scrutiny of current methods of handling food and equipment in restaurants and canteens; with, of course, disquieting results. Our alimentary juices have, in the main, a short way of dealing with pathogens; otherwise none of us would be alive to study the question. American work [1] reported during the war has shown that crockery and cutlery are liable to be heavily infected after being washed; and it was even suggested that the presence of atypical coliform *Bact. aerogenes* might be used to indicate the quality of dishwashing, just as typical *Bact. coli* is used as a measure of water contamination. In 1945, Sydney Linfoot,[2] in a letter to our columns, reported that he had examined 20 cracked cups from public restaurants and had found various pathogenic bacteria in the cracks. In a study of current practice in eating-places, Marcella Higgins and Betty Hobbs,[3] working at the Central Public Health Laboratory at Colindale, have found that tableware is often contaminated by the method of drying. Bacterial counts may rise more than a hundredfold after crockery has been dried with a used cloth.

They visited some thirty different representative establishments, including school and factory canteens, cafés, public houses, and exclusive restaurants. Visits were made in the rush-hour and every kitchen was visited at least twice. The methods of washing-up in these kitchens were classified according to the equipment used: some had one sink only; some had twin sinks, allowing for washing and rinsing; some had a washing sink plus a sterilising sink maintained at a constant temperature; and some had dishwashing machines. Yet in the end it was not the equipment so much as the washer-up that mattered: "even if the equipment is satisfactory, failure on the part of the operatives can completely neutralise any advantage that might be expected." Rinsing water quickly becomes contaminated unless it is very hot (not less than 180°F) and often changed. A really hot final rinse almost sterilises the crockery, and it will then dry quickly, in a rack in the air, without the need for drying with a cloth. Hypochlorite added to the water will sterilise utensils so long as the rinsing water is free from carried-over protein matter; but it leaves an objectionable taste on glasses and cups, and thus needs to be rinsed off. The United States Public Health Service have suggested a standard of less than 100 organisms per utensil as a measure of satisfactory washing-up, but none of the establishments visited could have passed this test. The group which came nearest were those in the third class, equipped with a sterilising sink maintained at a constant temperature: more than two-thirds of the utensils in these kitchens would have reached the U.S. standard.

Surprisingly, these workers found no special dangers in cracked crockery: "cracked cups washed under the same conditions as whole cups can have bacterial counts of the same order." And both cracked and whole cups which had counts in the hundreds before cleaning gave counts of less than 10 organisms per cup after immersion for two minutes in rinsing water at 180°F and air-drying. The battered homes of England will be glad to get this news.

TERRAMYCIN

SINCE 1939, when Dubos isolated gramicidin from the common soil organism, *Bacillus brevis*, the soil has been a prolific source of new antibiotics. Dubos foresaw that it would be, for he worked on the hypothesis that the relative absence of pathogenic bacteria in normal soil—with a few notable exceptions, such as anthrax, tetanus, and other clostridia—was due to the inhibiting substances elaborated by non-pathogens. The order of actinomyces, and particularly its streptomycetes family, has proved specially rich in useful antibiotics, though it has needed a vast amount of searching to produce streptomycin, 'Aureomycin,' chloramphenicol, 'Neomycin,' and some half a dozen others with more restricted fields of activity.

The new antibiotic, 'Terramycin,' reported in the U.S.A., also comes, as its [illegible] a soil actinomycete—a new one call[illegible] *osus* because of the cracked appearance of the surface growth on agar. So far as can be gathered from the brief account by Finlay and his colleagues,[1] of Messrs. Pfizer & Co.'s research laboratories in Brooklyn, terramycin has valuable properties in common with aureomycin and chloramphenicol, particularly that of being active by mouth as well as by injection. Preliminary studies in the chick embryo show activity against rickettsias and, in high concentration, against a strain of influenza A virus. Being amphoteric, terramycin can form a hydrochloride and a sodium salt. Its solubility in water at 25°C is about 0·25 mg. per ml., and the aqueous solution keeps well at room temperatures. Its toxicity to animals is low: in mice there were no deaths after an intravenous dose of 103 mg. of the hydrochloride per kg. of body-weight, and the L.D._{50} was 192 mg. per kg. Both in vitro and experimentally in mice it is highly active against *Strep. hæmolyticus*, *Strep. pneumoniæ*, *Bact. pneumoniæ*, and *S. typhi*. In an agar streak, *Ps. pyocyanea* was 100 times and *Proteus* more than 1000 times as resistant to terramycin as *Staph. aureus*; but these are notoriously tough nuts.

back and forth among the nations. In the same period again the intellect has evolved, and the emotions have seized, weapons able, we hear, to destroy us all. We have already witnessed the destruction of much of our existing civilisation by men who still lead us; and we are the peoples whom they were so easily able to lead only five years ago.

On two scores war is outdated: it has become unnecessary, and it has become suicidal to the more sapient trends of our species. But still wars arise in the minds of men—as the ski-ing pupil leans inward towards the slope—from instinct and habit. We are unable to install a cooler, more objective intellect in the place of the emotion-ridden intellect that huddles round the camp fires of yesterday.

LAW AND THE POWER-GROUP

Wars arise, and must continue to arise, in the emotional minds of ordinary men. In personal relationships and within the State those wars are checked by law: throughout history and throughout the world the spheres of law and order run concurrently and coterminously. But the law is given to man by his power-group and it is maintained by his power-group. Right up to now, power-groups themselves have had to be combative: there has been no law for them.

A hundred years of Europe show that the nation State is true to its inheritance. Once France was beaten (said the English) Europe would have peace. Then Russian barbarity had to be somehow settled in the costly and futile Crimean War. Palmerston's feint against the Federal States of America just failed to come off as a trans-Atlantic war in 1861. But behind France and Russia and the U.S.A. was Germany (twice), and behind Germany is Russia again. Behind Russia, if the impact comes and nation States survive it, will be China or America, or something perhaps to balance and attack that United States of Europe which has become the end rather than the means among the more gradualist internationalists of today.

If our argument is sound, no form of United States is big enough for the task in hand. Our human need is not to enlarge the group but to abolish the group. The power-group is no longer necessary. Its inescapable claim of "sovereign" decision of its own cause is anarchic. The one thing the human intellect cannot do is to judge its own cause—a fortiori its own group cause. International tensions and even "internationalism" must give place to world citizenship; national and federal government have to be converted into World Government. Then only will the minds of men cease from creating endless wars. For then the set-up is shifted to the already familiar framework of overriding law which protects us even against ourselves.

WORLD GOVERNMENT

Here we take our deep breath and make our mental jump: only to find that lots of people are over that fence before us! I am credibly informed that among advanced students of economics and political science everyone everywhere is in favour of World Government. The trouble in their minds, I am told, is that A (say, Russian National Communist leaders today) wants World Government on A's theory of government and B (say, Britain's National Socialist leaders today) wants World Government on B's theory of government. And so on.

It is something to know they want World Government, or even to grasp that here and there able men in high places in all countries are beginning to see its need as the single alternative to the chaos of our world. The final problem to be resolved is this: Do A's and B's theories of government differ as much as they each think they do? Do the requirements of the good life for A's people and B's people differ materially at all? Ideologies comprise ideas. Ideas can be pooled and they can be modified. Human nature is essentially one in its needs of food, shelter, work, leisure, inspiration, love, and peace. War is what the nursery accepts till a grown-up enters with a better way, introducing positive law and the elements of good government to the inmates. The world requires a World Council of wise men to find the common denominator of the good life as seen and as wanted by A, B, C. and D.

A recognition by all parties that the actual needs of their peoples are the same only requires an inhibition by enough higher intellectual centres of the reflex arc which still makes wars arise in the minds of men. The process required is that Philip sober shall arrange for the treatment of Philip drunk, which is what all good democrats and Communists already have to do in approving the restrictive legislation of their own States.

One topical word to us all as potential world citizens. "Seek out thine *adversary* and agree with him!" Try to find out what A really wants, just supposing you are B. If you find you are angry with Stalin, what you most need is to enter into a common legal system with him. You will never be quite safe till you do!

If that really is "quite impossible" then it looks as if we shall have to let our minds go on raising wars. That it is natural for us to *think* it impossible, without its necessarily being so, is the main burthen of my argument: our emotionally directed intellects are so conditioned. But if it is impossible for us even to try, there is still just one thing we can do, apart from being "strong" nationally which (though being weak seemed to lead the same way in 1939) has always been a royal road to war. It is to use our 1950 intellects to set up a pooled authority of *all the rest of us*, temporary friend and temporary suspect alike—a system of law into which Russia can come when she will. If it is stronger demonstrably and beyond a peradventure than anything that can attack it, it will keep the peace till she does.

This is the same system that would have kept the peace in the wasted '30s. It is not the same as having a screen of League or United Nations behind which each nation is nationally "strong." That method only frees the conscience of your adversary and spurs him to become stronger still, to detach your wavering allies, and to hit you off your guard. It means a legal order establishing the system of positive law for which Hobbes pleaded in England in 1651, and which, thank God, we got in England in 1688—a system that keeps us all in order.

Only conventional thinking makes so many of us think it impossible to set up the World Government for which the present situation so urgently calls.* It must presumably be some sort of democracy; it must plan to become world-wide; and it should be characterised by all possible tolerance for ideologues of Left or Right, of East and West. But there must be no nonsense at all about its legal system. Since of their very nature men need a power to keep them all in awe the system of World Law must secure the world against group violence from anywhere, and it must place the force of a constant majority of power behind that law. In respect of World Law national armies are private armies, national navies and air forces private navies and air forces. The British Army and the United States Air Force, pleasant and goodly in their ways, are anachronisms of world order, and, though their friends find this difficult to believe, they frighten away just as many neighbours as they rally to their side. What is needed is World force behind World Law guaranteed by a world democracy—excluding Russia if she dislikes and distrusts your previous systems and policies too much to accept anything you do. It

---

* That may be why more minds in less conventional America have now reached the point of thinking calmly and practically about world government and World Law.

With adults as with infants, in balancing, righting, or whatever the reflex, the matter of first importance is the appropriate response; of next importance is the storing of the experience to facilitate further and better responses in future; of least importance is a correct evaluation of the events in train, their significance, their "truth." This *applies to all biological* "*instinctive*" responses, which are firmly grounded in the race and only to be slightly modified in the individual.

THE RÔLE OF INTELLECT

But though it may have been originally a mere by-product of sensation, *Homo sapiens* has greatly developed the human intellect, into an aid to quicken effective response in certain situations. As a function it has become of great importance in adjusting the organism to situations that are not susceptible to instinctive reflex response because they are new and require new responses rapidly arrived at. Such situations have met us in the past history of our race, and our ancestors have secured their survival—as individuals, as groups, and perhaps even as race and species—by intellectual processes such as logical inference, inventive skill, and endless "taming of nature."

Changing circumstances assail mankind today. We could cower and take cover "instinctively" against bow-and-arrow attacks; we have to learn intellectually how to take cover in modern warfare. We instinctively cling to a steepening slope with all four limbs; but that is not the response that brings us safety when we go on skis. Intelligence is a late development of man, introduced, as I see it, to aid his appropriate motor responses, but not necessarily to tell him the truth.

Once we adopt this view of intelligence we seem to understand more easily many patterns of the mind. For instance, an intellectual appraisal accompanies all loving and hating; but it is the loving and the hating that are the appropriate responses; the intellectual appraisal merely sustains them, and it is often false.

There is a difference here between individual and group response. In our individual lives our biased judgments may find some useful correction in respect of objective truth from the less passionate judgments of our fellows. But in group relations this is not usually necessary, nor does it often occur. For group safety depends upon passionate devotion in a way that individual safety does not. *There is traditionally no very obvious use for the* truth in group relations.

When we consider how much ardent loving and hating are necessary to induce adequate responses of loyalty and self-sacrifice from individuals to groups, we begin to understand why our judgments of, say, the French, German, Russian, or American nations fluctuate, in the way they do, in terms of how those nations stand in relation to our national family and its hopes and fears of the moment. There is very little objective about war-time judgments; but, though they are the more strikingly absurd, they partake of the same qualities as our judgments of those we love and hate, of ideas we trust or fear in our intimate daily life. It is the same thing, writ large because shared and uncorrected by any *cross-currents of different* experience. All judgments are emotional; all emotional judgments are biased; and power-group political judgments are peculiarly and fantastically biased.

Since some emotion enters into every judgment we can begin to speak of prejudice in judgment as universal and inevitable. Our judgment is not there to give us the truth but to help us to achieve something. In group relations that something has through age-long history required from us passionate loyalty, fear, hatred, and greed. It has required hot enthusiasm from the heart: cool and logical intellectualism were nothing but a menace to group security in the days that are past. The group still makes these demands, and that is why group judgments and conduct, even more than individual *judgments and conduct, need the* control of positive law today.

IV. A Present Use for the Intellect

In a previous section I said that in this our era of the nation State every war between nations is caused by nationalism and fought in patriotism, and that if a war starts under any other guise it is never fought *for long* before that guise is stripped off. Ideologies flit and hover: they may flit in and out of a political party within ten years; they may hover for fifty years, but seldom, unmodified, for more. I have further suggested that it is not any divergence of structure of the human mind, or even any difference of content of the human mind, that causes wars to arise, but their similar pattern and their similar content. This common combat-inducing quality of the mind of man is loyalty to his power-group.

To establish such a proposition it is necessary to cite good evidence of the common content of the human mind in respect of basic group emotion, and to be able to point to the common behaviour resulting. Each of these heads could reasonably receive far fuller and more convincing *treatment than is accorded it in this article,* which contains a mere outline of an argument which I believe to be valid.

GROUP LOYALTIES AND A NEW SITUATION

I have thought it fair to assert that in respect of group loyalty we do behave in a common way, and that we do so instinctively rather than intelligently. We do so without realising it. And, in the sense that we foster upon our temporary enemies all the evils we can *think* of—before feeling ourselves forced to fight them—*war-mindedness is indeed a form of intellectualisation* so falsifying as to amount to insanity. Like other lunatics, we rave, we wreck, we kill, believing in our frenzy that there is no other way.

One would like to find a name for the insanity that leads prejudiced human beings to death in a group cause which was once a good cause but which is so no longer. Perhaps "fanatical loyalty" will serve: terms borrowed from individual psychiatry tend to be misleading.

Both this furious emotional antagonism and its accompanying intellectual processes were designed by *nature to nerve us for one purpose only*—to fight loyally for our allotted group against its enemies. Loyalty to the death needed a powerful mechanism to excite it and maintain it. We still see that powerful mechanism ready *to go into operation automatically* today.

But it so happens that such loyalties, such *routine* group emotions, have suddenly become out of date and hideously inappropriate. Again we seem to be for the most part totally ignorant about what has happened or where we stand. For æons our group response to competing groups has been hostility and attack. We are used to that. The accompanying mental state in such fanatical loyalty has been compounded of hostility *and fear:* hostility to aid the attack, fear to aid the withdrawal or surrender which may be needed to secure a limited survival—responses each of which may suddenly become *appropriate.*

What is the appropriate response today? A new set of achievements by that one-time paraphenomenon the human intellect has suddenly presented us in half a century with a world in which other groups need not menace us, nor we them, because there is food enough (though only just) for us all. The human intellect can organise the production and distribution of that food. Humanity has resources which enable the world *to* be run at last as One World. But the fearful, old-fashioned mind of man has filled this same half-century with wars *inspired by fears and jealousies knocked like shuttlecocks* every day. This is a great help to all of us and we take a proprietary interest in each other's progress, with very stimulating results, physical as well as psychological.

I am full of admiration for the way in which preservation of body function, including balance, has been worked out, and am very proud of my first attempts to stand without support in bilateral calliper splints. It is clear that all measures taken with total function in mind will save time in the long run.

Two points about nursing have impressed themselves on my mind as of great importance to the patient. First, it is not always realised how extremely painful paralysed muscles can be, nor that the natural reflex protecting muscles against a pinch or knock by increase of tone is abolished. Thus, the not uncommon practice of picking up a limb by a muscle between finger and thumb is very painful. Limbs should be raised wherever possible by the hard bony points. Secondly, when there is upper limb paralysis, on no account must an attempt be made to hoist the patient by any form of traction in the axilla. This common practice inevitably stretches paralysed muscles, is excruciatingly painful for the patient, and cannot be too good for the muscle itself. The right way to raise such a patient is by passing the hand round the whole back and using the vertebral column itself, supporting the shoulders meanwhile. Similarly, the whole body must be raised by two people making a cradle.

RELATION BETWEEN PARALYSIS AND PREVIOUS ACTIVITY

The present condition of my muscles is of considerable interest when one considers which of them bore the greatest strain during that confinement now nearly three months ago.

The state of my muscles on Dec. 5, 1949 (day 39) and on Jan. 2, 1950 (day 67), was plotted on a six-point scale as follows:

0, no muscle reaction
1, flicker present
2, visible contraction
3, movement if supported
4, movement against gravity
5, movement against resistance

Left side Day 67	Day 39	*Muscle action*	*Right side* Day 39	Day 67
Lower limb—				
4	4	Dorsiflexion	0	0
3	3	Inversion	0	1
4	2	Eversion	0	1
3	3	Plantar flexion	0	1
4	3	Intrinsics	0	0
2 +	2	Hamstrings	1	1
2	2	Quadriceps	1	1 +
1 +	1	Abduction	1	1
2	1	Adduction	1	1 +
2	2	Glutei	2	2
Upper limb—				
4 +	4	Flexors of fingers	4	4 +
4 +	3	Opposition of thumb		5
4 +	3	Flexors of wrist	3	4
5		Extensors of fingers		1 −
4		Extension of thumb		1
4	3	Extension of wrist	1	1
4	3	Pronation	2	3
1 −	0	Supination	0	1 −
2	2	Biceps	1	1
1	1	Triceps	1	1 −
1	1	Deltoid	0	1 −
Trunk—				
5	4	Abdominals	4	5
1 +	1 −	Pectorals	1	1
5	4	Trapezius	4	5
4	3	Erector spinæ	3	4
4		Rhomboids		4

The *left leg* has slowly but progressively improved, though none of the muscles can as yet act against gravity. The weakest muscles are the gastrocnemius/soleus and the internal rotators of the thigh. It was the plantar flexors of this leg which had most to do at the confinement.

The *right leg* is much weaker than the left, and so far there is no recovery below the knee. The thigh and hip muscles all show some signs of life, the weakest appearing to be the rotators of the thigh. The weakness of gluteus maximus is surprising; but when the use of the right leg for countertraction is remembered everything again fits in.

The *left arm* is much stronger than the right. The power in the left hand is very good, and I am, in fact, correcting this typescript with it. The chief difficulty is not the unusual task of writing left-handed but the weakness of supination and the tendency of the hand to fall on to the thumb. The wrist, too, is good and can act against resistance. Biceps and triceps are improving; but the weakest muscle of the whole limb is the deltoid, which has only shown some real flickers of contraction in the last fortnight.

In the *right arm* the only muscles with any power are the flexors of the fingers and wrist and the lumbricals. There are now slight flickers in the extensors of the wrist and the biceps, while triceps and deltoid are doubtful. The right shoulder-girdle muscles are weaker than the left though in fairly good condition.

The *trunk muscles* have recovered very well and I can now easily sit up without support.

The clear parallel between muscular activity in the early stages of the disease and the resultant paralysis and paresis seems worth recording.

Another question that occurs to me concerns the vague cerebral symptoms which occurred in my preparalytic and early stages—feeling of nystagmus, difficulty in swallowing, inability to purse the lips for whistling, and the one transient sign, ptosis. To what extent had these anything to do with the infection?

I am indebted to Mr. K. F. Hulbert, orthopædic surgeon to the Southern Hospital, Dartford, Kent, for permission to use the muscle power-charts.

Medicine and the Law

Blood Donor's Claim for Damages

A LADY who, five years ago, joined the local blood-transfusion service as a donor, unfortunately contracted a septic arm after her ninth donation, the previous eight occasions having had no ill effects. Alleging negligence in the operation, she claimed damages from the Ministry of Health (as statutory successor of the legal liabilities of the hospital concerned) and also from the doctor who performed the extraction.

Her evidence was that on the ninth occasion the doctor seemed to take a long time in finding the place in her arm in which to insert the needle; after her ten minutes' rest she noticed that there was bleeding from the puncture; she said that she reported this to the hospital sister (though this was denied) but was assured that all was well. She said she went home as usual but her arm subsequently swelled; she was admitted to hospital and remained there for about a month. Her own doctor gave evidence that he found an infected clot in the region of the right elbow. He agreed in cross-examination that it would be prudent and careful on the part of a doctor, in dealing with a plumpish patient, to take a little time before making the incision; he found no sign that the incision had been made otherwise than carefully and properly.

Doctors and hospitals, needless to say, do not guarantee patients against all ill effects of medical treatment; they cannot be made to pay damages unless some act of negligence is established. The allegations of negligence here were twofold—first that the hospital staff failed to take adequate antiseptic measures, and secondly that, when bleeding was reported to the hospital sister, there was a failure to examine the puncture and to replace the sodden bandage which would form a culture-medium. On behalf of the defendant doctor his counsel submitted that there was no case of negligence against his client for the jury to consider. Mr. Justice Hilbery deferred decision until the case against the hospital had been heard.

For the hospital the sister testified that there was nothing unusual about this blood extraction. Evidence must, however, be Russia excluded because she won't come into the scheme when it is fully prepared, published, and operable, and not Russia excluded because somebody on our side says she won't come in.

With or without the adherence of every single Great Power—though better with than without—a pooled world order to which all national sovereignty gives pride of place will secure what no national diplomacy can possibly secure—a clear and safe majority of world power for peace. Since Russians too are human, I think the sound psychologist can foretell that it will also secure them.

A SUBJECTIVE VIEW OF ACUTE POLIOMYELITIS

This account of his own case has been compiled from the dictation of an experienced general practitioner, aged 40, who is now in hospital recovering from extensive paralysis.

* * *

I had been working fairly hard in a busy south-east London practice, but had arranged with my assistant to attend a week's refresher course in midwifery at Brighton. On Friday, Oct. 28, during the course, I was not feeling well, with general malaise and tiredness. During the morning a strange feeling of giddiness in the eyes developed. It was as if my eyes were moving from side to side, as in nystagmus. This was a horrible sensation which made me dizzy, and, in spite of the uselessness of doing so, I found myself repeatedly looking in the mirror to see if I could detect any nystagmus.

This eye symptom continued during Saturday, and I drove home from Brighton very slowly and with some difficulty because of my visual discomfort. There was no impairment of visual acuity. On Sunday, the 30th, I consulted an ophthalmologist colleague because, although the symptom had practically disappeared, I was concerned about it; however, there was nothing wrong with my eyes at the time of the examination.

My main symptom on the Sunday was weakness, and I went to bed in the afternoon. Precisely 10 minutes later I had an urgent call to a confinement, and had to dress and go out again. Fœtal distress was obvious on my arrival, so I had to apply forceps at once and attempt to deliver the baby as soon as possible.

I am almost ambidextrous, with a slight right-hand dominance. With my patient in the lithotomy position I exerted traction mainly with the right arm but using my left arm when tired. Counter-traction was provided by my right leg pressing on the bar at the foot of the bed while I was standing on the ball of my left foot. It will be seen that the muscles used mostly in this $1^1/_2$ hours of vigorous exertion were: in both arms, though the right more than the left, the deltoid, both biceps and triceps as "fixers" of the arm, and the extensors of the wrist; in the right leg, the extensors of the thigh (glutei) and quadriceps and all muscles below the knee as fixers; in the left leg, the plantar flexors.

On Monday morning I felt very ill, with nausea and vomiting and a severe headache. My temperature was normal. I tried to get up but had to return to bed. The severe headache, and the generalised limb and body pains which began later, persisted for four days. On the Tuesday the superintendent of a London fever hospital was called in consultation, but apart from the general malaise there was no other sign of illness. There was, however, at that time, a slight right-sided ptosis which passed away after a few hours; and a difficulty in swallowing solid food which lasted for about a week but was associated with no diminution in movement of the uvula.

My temperature rose to about 100°F for the first time on Wednesday. Having been constipated since the Saturday, I was given an enema that evening; and later in the night, feeling extremely ill, I went to the toilet where I discovered that my right arm was almost completely immobile and my left arm was very weak. From that moment I was convinced that I had poliomyelitis, yet for the next three or four days the pain from piles which had prolapsed under the influence of the enema and had partly thrombosed because I had been unable to reduce them, occupied my mind almost to the exclusion of my more serious trouble. Such is the constitution of the human mind.

I was admitted to a fever hospital on Thursday afternoon, Nov. 3, six days after the first symptom. Subjectively, on admission my right arm was completely paralysed but on the left side slight hand movement remained. For the first two nights in hospital I could ring the hand push-bell placed in my bed, but on the third day even this power in my left hand disappeared. My impression is that the functions disappeared in the upper arms before the lower arms and in the right arm before the left. I had no incontinence and no loss of sensation at any time. I became aware of slight neck-rigidity, on examination, causing severe pain which radiated right down the back, and of a positive Kernig's sign.

In parenthesis, the prospect of a lumbar puncture was frightening but a thorough infusion of local anæsthetic was made and I did not realise when the actual puncture was performed. It was completely painless, and I found it trying only because of my impatience to have it finished. The only noticeable after-effect was a severe head pain for some hours on the slightest movement of my head. The elicitation of a positive Kernig's sign—i.e., stretching of the hamstrings—is the most painful sensation I have ever experienced. May I recommend tenderness?

My temperature returned to normal on Nov. 4, and has remained so ever since.

On Sunday, Nov. 6, a week after I attended the confinement, my legs became weak, the right before the left side, and by Tuesday both were completely paralysed from the hips downwards except for slight movements in the left foot which have been present throughout.

A little symptom, which is almost laughable in retrospect but was worrying at the time, was that, with my almost complete loss of self-expression except for talking (and I had a distaste for a surfeit of talking to myself), I resorted to whistling to keep my courage up, only to find to my dismay that this was impossible during my first week in hospital. I was unwilling to bring this new worry to the notice of my medical attendants in case they found out something still worse about me. At the end of the week my whistling powers returned, much to my relief. These little details may loom very large in the patient's mind when he has little else to do but meditate on his condition. I had no respiratory involvement at any time, I am thankful to say.

As soon as my confidence began to return I discovered that the lumbrical muscles in both hands seemed to be working, stronger on the left side.

REABLEMENT AND NURSING

At the time of writing, on Jan. 20, six weeks after my transfer to a general hospital for physiotherapy, I am getting much satisfaction from the rehabilitation routine and am taking great pride in each new return of function. I take it that preoccupation with minute details of recovering muscular power is inevitable, and so long as improvement is progressive this is a good thing.

Here all the adult patients of both sexes recovering from poliomyelitis join together in a class for exercises every day. This is a great help to all of us and we take a proprietary interest in each other's progress, with very stimulating results, physical as well as psychological.

I am full of admiration for the way in which preservation of body function, including balance, has been worked out, and am very proud of my first attempts to stand without support in bilateral calliper splints. It is clear that all measures taken with total function in mind will save time in the long run.

Two points about nursing have impressed themselves on my mind as of great importance to the patient. First, it is not always realised how extremely painful paralysed muscles can be, nor that the natural reflex protecting muscles against a pinch or knock by increase of tone is abolished. Thus, the not uncommon practice of picking up a limb by a muscle between finger and thumb is very painful. Limbs should be raised wherever possible by the hard bony points. Secondly, when there is upper limb paralysis, on no account must an attempt be made to hoist the patient by any form of traction in the axilla. This common practice inevitably stretches paralysed muscles, is excruciatingly painful for the patient, and cannot be too good for the muscle itself. The right way to raise such a patient is by passing the hand round the whole back and using the vertebral column itself, supporting the shoulders meanwhile. Similarly, the whole body must be raised by two people making a cradle.

RELATION BETWEEN PARALYSIS AND PREVIOUS ACTIVITY

The present condition of my muscles is of considerable interest when one considers which of them bore the greatest strain during that confinement now nearly three months ago.

The state of my muscles on Dec. 5, 1949 (day 39) and on Jan. 2, 1950 (day 67), was plotted on a six-point scale as follows:

0, no muscle reaction
1, flicker present
2, visible contraction
3, movement if supported
4, movement against gravity
5, movement against resistance

Left side Day 67	*Left side* Day 39	*Muscle action*	*Right side* Day 39	*Right side* Day 67
Lower limb—				
4	4	Dorsiflexion	0	0
3	3	Inversion	0	1
4	2	Eversion	0	1
3	3	Plantar flexion	0	1
4	3	Intrinsics	0	0
2 +	2	Hamstrings	1	1
2	2	Quadriceps	1	1 +
1 +	1	Abduction	1	1
2	1	Adduction	1	1 +
2	2	Glutei	2	2
Upper limb—				
4 +	4	Flexors of fingers	4	4 +
4 –	3	Opposition of thumb		5
4 +	3	Flexors of wrist	3	4
5		Extensors of fingers		1 –
4		Extension of thumb		1
4	3	Extension of wrist	1	1
4	3	Pronation	2	3
1 –	0	Supination	0	1 –
2	2	Biceps	1	1
1	1	Triceps	1	1 –
1	1	Deltoid	0	1 –
Trunk—				
5	4	Abdominals	4	5
1 +	1 –	Pectorals	1	1
5	4	Trapezius	4	5
4	3	Erector spinæ	3	4
4		Rhomboids		4

The *left leg* has slowly but progressively improved, though none of the muscles can as yet act against gravity. The weakest muscles are the gastrocnemius/soleus and the internal rotators of the thigh. It was the plantar flexors of this leg which had most to do at the confinement.

The *right leg* is much weaker than the left, and so far there is no recovery below the knee. The thigh and hip muscles all show some signs of life, the weakest appearing to be the rotators of the thigh. The weakness of gluteus maximus is surprising; but when the use of the right leg for counter-traction is remembered everything again fits in.

The *left arm* is much stronger than the right. The power in the left hand is very good, and I am, in fact, correcting this typescript with it. The chief difficulty is not the unusual task of writing left-handed but the weakness of supination and the tendency of the hand to fall on to the thumb. The wrist, too, is good and can act against resistance. Biceps and triceps are improving; but the weakest muscle of the whole limb is the deltoid, which has only shown some real flickers of contraction in the last fortnight.

In the *right arm* the only muscles with any power are the flexors of the fingers and wrist and the lumbricals. Her own doctor gave evidence that he found an infected clot in the region of the right elbow. He agreed in cross-examination that it would be prudent and careful on the part of a doctor, in dealing with a plumpish patient, to take a little time before making the incision: he found no sign that the incision had been made otherwise than carefully and properly.

Doctors and hospitals, needless to say, do not guarantee patients against all ill effects of medical treatment; they cannot be made to pay damages unless some act of negligence is established. The allegations of negligence here were twofold—first that the hospital staff failed to take adequate antiseptic measures, and secondly that, when bleeding was reported to the hospital sister, there was a failure to examine the puncture and to replace the sodden bandage which would form a culture-medium. On behalf of the defendant doctor his counsel submitted that there was no case of negligence against his client for the jury to consider. Mr. Justice Hilbery deferred decision until the case against the hospital had been heard.

For the hospital the sister testified that there was nothing unusual about this blood extraction. Evidence was given that the instruments were sterilised with the most modern apparatus and that the standards of practice were high. A surgeon supported the latter point and told the court that it was impossible absolutely to sterilise the skin; even in the most hygienic conditions, with a clean operation conducted in a perfectly sterilised theatre, there was always some risk of sepsis.

The learned judge ruled that there was no case against the defendant doctor; the claim against him was dismissed with costs. As regards the hospital, on whose behalf it was urged that there was no proof either of an omission to employ proper antiseptic measures or of any breach of duty on the part of the staff, the jury (after a three hours' retirement) awarded £200 damages. The judge granted a stay of execution with a view to an appeal. He expressed sympathy with the plaintiff, who had met with this unusual and disagreeable experience in voluntarily performing her act of service to the community.

Burns from Domestic Fires

The deaths of three women who were burned in their nightclothes were investigated by the Battersea deputy coroner on March 2. "Fire brigade officers," he stated,[1] "say it is possible to be as much as 18 in. away from an electric stove and still start a fire. Nightwear is often so flimsy that it can be alight before the heat is actually felt."

At the end of last year the Manchester coroner observed that within a few months he had investigated seven fatalities from electric fires; "it is time somebody woke up and did something about it."[2] The perils of electric and gas fires have been discussed in these columns by Dr. and Mrs. Colebrook.[3]

Burn From Hot-water Bottle

At Bristol Assizes on Feb. 13 a jury awarded £650 damages against a nursing-home on a claim alleging that a newborn baby had been negligently placed in a cot with a hot-water bottle and had thereby suffered disfiguring burns on the thigh and leg. The sum awarded included £150 as the estimated cost of a future skin-grafting operation. A claim against a doctor was dismissed. One of the questions in the case was whether a nurse or the doctor placed the baby in the cot. The accident occurred in January, 1947; apparently it was not until May, 1949, that any allegation of blame was made against the doctor.

The matron of the nursing-home was questioned about an entry in her register. It ran as follows: "On bathing baby, right leg badly marked, possibly by excessive heat during or immediately after resuscitation." In cross-examination she agreed that the register was kept for the medical officer of health; the entry was intended to make him believe that the baby was burned or injured while in the labour ward. The doctor gave evidence that, to resuscitate the child, she had placed it in a warm bath and carried out artificial respiration. The entry in her own records was "baby had burn right thigh." She denied a suggestion that she had dictated the entry in the matron's register. She did not know who placed the child in the cot.

Mr. Justice Lynskey told the jury that doctors and nurses are trained to deal with crises, but, though there is an emergency, they are liable if they are guilty of carelessness. It was understandable if they made a mistake, but it was not excusable in law; they must take reasonable precautions at all times. The nursing-home was directed to pay the costs of the doctor as well as those of the plaintiff.

In England Now

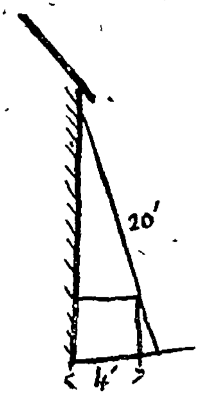
A Running Commentary by Peripatetic Correspondents

AMONG the maxims decorating my desk is one which reads "Have I got toothache, earache?" intended to combat the blackest moments of depression. Now I am thinking of adding a new one, inspired by not seeing my face in your noble portrait gallery of medical M.P.s. Poor chaps: twenty letters a day, each asking an apparently insoluble question which must be answered for fear a vote is lost. Every other Saturday and Sunday off to the constituency to spout or be spouted at. Then the dreary hours in that Chamber of Little Ease, the House of Commons. The certain knowledge that every easy chair in the Library has already been pinched. The great speech one waits three days to make, immortalised in the *Times* with "Dr. So-and-so also spoke." The endless heartiness and good fellowship. The daily cost of meals. The parties of school-children to be shown around the House. The clock-tower to be climbed once a month with the Boy Scouts. The smell of a division lobby at four in the morning. The boredom when one sticks out the late debate; the pangs of conscience when one cuts it. The visitors to be found seats, the deputations to be listened to, the never-ending stream of papers to be read. The thousand pounds a year that goes nowhere and leaves no time or energy for earning anything else.

And yet, on second thoughts, I doubt if I dare add that maxim yet. I have the awful feeling that before long I may again be inviting the suffrage of the electors of Eatanswill. Afterwards, I shall certainly commiserate with the victors and congratulate the defeated on their lucky escape.

* * *

Do you know the problem of the twenty-foot ladder, the house, and the box in the shape of a four-foot cube? The box is on the ground against one wall of the house and the ladder is leaning against it and the wall, as per diagram. How high up the wall can the ladder reach?



We first met this problem at Christmas when visiting my relations, who had got it out of one of the intelligent weeklies. An evening or two of trigonometry, algebra, and trial and error (especially error) produced various solutions like $0=0$, or $1=1$, and equations like $x^4-4xy=y^3-384$; but at last, with the aid of the baby's bricks, we got the answer. After our holiday I felt it was only fair to tell my colleagues about it. Their keenness was astonishing. Usually they said: "Well, it's simple enough. *This* angle equals this. . . . Well, anyway, *this* side is x, and $y-4$ is the height from here to here . . . and, no, that won't do . . ." and they would then retire to work it out in private. The real zenith of keenness was reached by the four registrars, who went at it till 2 A.M. on two successive nights. The surgical staff produced pages of careful calculations, but no solution. In a week or two, people were showing it to me as a problem I might like to try, but their manner did not encourage me to reveal that I had instigated the whole thing. Even now several blotting pads in different parts of the hospital still show the diagram, with fragments of calculation, and it can also be seen on the wall in one of the corridors. Only last Friday the pædiatrician produced two entirely new solutions by an uncle of his who had just decided to retire from his very promising political career and give his whole time to the problem.

* * *

I am fortunate in having two lady friends who are physiotherapists (they are still old-fashioned enough to be proud of the name "masseuse"). We have a mutual agreement concerning our personal attacks of fibrositis, if one may still use that term—I charm theirs away with Novocain while they rub mine away with Great Gusto.

[1] *Evening Standard*, March 2, p. 3.

[2] *Lancet*, 1949, ii, 1204.

[3] Colebrook, L., Colebrook, V. *Ibid*, p. 181.

The other day I was foolish enough to voice a hidden fear that I am becoming fat and flabby. The effect was electric. Their heads shot up, their eyes glistened, and their nostrils quivered like a dog's when it is on the track of some particularly revolting scent. An invisible message passed between them and with one accord they uttered the magic word "HORNIBROOK'S." This, I learnt to my increasing horror, is the eponymous classification of a series of fiendish exercises designed for people of my incipient size, and in the best of spirits they proceeded to initiate me into the mysteries of their art.

I will not describe the voyage of impossible and indecent contortions on which I embarked. To them I was but a bundle of levers, prime movers, and antagonists, and did I raise but the slightest whimper I received in return a relentless glance and a muttered "Hornibrook." At last it was over, and I was led gently out into the cold air and placed in the driving seat of my car. As I put down the clutch pedal, the younger and kinder of the two leant in at the window, whispering, "I shouldn't repeat these for a few days, if I were you. You *might* cause a hernia."

I have gained 6 lb. in the past month and I still have nightmares in which a fiend answering to the name "Hornibrook" carelessly ties me into a surgeon's knot.

* * *

My seven year-old daughter and I set off the other day to deliver invitations to a party. Most of them were to medical colleagues living in our street. We found to our disappointment that the invitation cards were too big for the letter-boxes. But when we reached a black door with a huge plate and unhappy memories of a dental drill the card went in with no trouble at all. "Mummy, do you think the door's been listening at key-holes? Uncle K always tells me to 'open a little wider' even when I stretch so hard it hurts." Maybe it had; who knows? The child's habit of giving human attributes to inanimate objects opens up delightful possibilities. When my husband picked up his bag at 2 A.M. the other morning I swear I heard the bag say: "Have a heart: I'm closed for the night."

* * *

The influence of the recent election even extended to our gynæcological clinic. One patient, questioned about the state of her leucorrhœa, replied: "It's much better now, but it's changed its constituency." Our offer to treat her in a different ward was refused.

LAMENT OF A LABORATORY LIBRARIAN

When a doctor's not engaged on his dissections and injections,
Or in chasing little microbes up a sewer,
He will delve into the mysteries of recondite case-histories
With references exotic and obscure;
A symposium in Spanish about mumps in Machrihanish
With a footnote from Guadeloupe on glands,
A report on sudden death by a lady called Macbeth,
With the title "Don't forget to wash your hands."
Through labyrinths of literature on frailties of the flesh
I search from crack of dawn till set of sun.
Ah, who would be a handmaid of the medical profesh?
The librarian's lot is not a happy one.

"An infection found in beavers was transmitted to retrievers,
And carelessly contracted by a vet,
While the organism, injected in a toad in Timbuktu,
Was recovered from a tadpole in Tibet.
Now, was it in the *Lancet* in 1892?
Or the *B.M.J.* in 1923?
Or maybe *Path. & Bact.*? No. I can't be more exact,
And I think the name was Smit, or Smut, or Smee."

Good sons of sage Hippocrates and Galen's gallant heirs,
May your battle with the bugs be timely won,
But spare a pang of pity for the writer of this ditty.
The librarian's lot is not a happy one.

Letters to the Editor

EXPERIMENTAL PRODUCTION OF MALIGNANT TUMOURS BY BERYLLIUM

SIR,—In 1946 Gardner and Heslington[1] reported the production of bone sarcoma in rabbits by the injection of suspensions of zinc beryllium silicate and beryllium oxide. Few details were given in their paper and nothing more has yet been published on this observation.

In 1947 the experiments of Gardner and Heslington were repeated by the Toxicology Unit of the Medical Research Council. A total of 28 rabbits survived a course of intravenous injections of zinc beryllium silicate and beryllium silicate. Of these 28 rabbits, 7 have developed bone sarcoma and 5 remain alive $2^1/_2$ years after receiving the injections. The tumours have all the histological characteristics of bone sarcoma seen in man. In this they resemble the tumours produced in rabbit bones by radium (Ross[2]). A full account of this experiment, written in collaboration with Dr. F. A. Denz and Dr. H. A. Sissons, is ready for submission for publication.

In March, 1949, a washed suspension of finely divided beryllium metal in water was received from the Atomic Energy Research Establishment, Harwell. A group of 24 young rabbits were given what was to be the first of a series of intravenous injections of this metal suspension. Each rabbit received 40 mg. of metal. Within seven days 9 rabbits died with acute liver necrosis and all the typical signs of acute poisoning by a soluble Be compound.[3] During the next month 10 more rabbits died and all showed a considerable degree of liver necrosis and fibrosis. Of the remaining 5 rabbits, 2 have died from pulmonary infections while 2 have developed characteristic bone sarcomata. There is a single survivor.

All the materials injected have been examined and found to be free of significant radioactivity.

There seems little doubt that beryllium itself can produce neoplasms in the rabbit, and the purpose of this letter is to draw attention to what might possibly be another industrial hazard.

DEOXYCORTONE ACETATE AND ASCORBIC ACID IN RHEUMATOID ARTHRITIS

SIR,—The preliminary communication by Lewin and Wassén[4] prompted me to try this treatment on some of my outpatients. I treated two patients with rheumatoid arthritis, two with advanced osteo-arthritis, and one with rheumatic fever.

CASE 1.—A man, aged 77, with polyarthritis, of 6 years' duration, involving both shoulders, the neck, and both hands. Ten minutes after the first intramuscular injection of deoxycortone acetate 5 mg. ('Cortiron,' Schering) followed in five minutes by an intravenous injection of ascorbic acid 5 ml. (1 ml. = 200 mg.), the patient felt better and thought that he could move his arms more freely. Thirty minutes later he was able to move his head and arms with great ease, so far as the anatomical changes in the joints would allow. This improvement lasted eighteen hours, during which time the patient was able to put on and take off his hat with comparative ease—which he had not been able to do for the past 3 years. After this period the patient promptly relapsed and exhilaration was replaced by depression.

On the next day he had an intravenous injection of ascorbic acid and an intramuscular injection of strychnine sulphate 2 mg. as control injections; but the pains, the spasm, and the joint movements remained unchanged.

---

1. Gardner, L. U., Heslington, H. F. *Fed. Proc.* 1946, 5, no. 1, pt. II.
2. Ross, J. M. *J. Path. Bact.* 1936, 43, 267.
3. Aldridge, W. N., Barnes, J. M., Denz, F. A. *Brit. J. Exp. Path.* 1949, 30, 375.
4. Lewin, E., Wassén, E. *Lancet*, 1949, ii, 993.

On the fourth day he had another intramuscular injection of deoxycortone acetate 5 mg. and ascorbic acid intravenously, and the result was exactly the same as on the first day; the improvement lasted this time 17 hours. On the fifth day the same procedure gave the same good result; improvement lasted 17–18 hours.

CASE 2.—A woman, aged 40, suffering for the past 18 years from rheumatoid arthritis involving almost all joints. She also had the same treatment but the ascorbic acid had to be injected intramuscularly, because of obesity. One hour after the injections the pain in the joints decreased slightly and she was able to close both fists for the first time in a year. The improvement lasted 8 hours. The next day she received the same injections with the same results.

CASE 3.—A woman, aged 50, suffering from severe osteo-arthritis of the neck and lumbar spine; X-ray examination showed that the disease was very advanced. On the day of treatment she had a very severe headache, from which she suffered frequently. Twenty minutes after the injections the headache had gone, but the pain in the neck was still very bad. Five hours later the headache returned; pain in the neck and back were slightly better. Twelve hours later the pain in the neck and back was still relieved and she could move more freely. This very slight improvement lasted twenty hours, after which all the symptoms returned.

On the third day she had another course of injections, and this time the headache cleared after ten minutes. She stated that all pains had disappeared; and for the first time in years was able to sleep without discomfort, being able to place her head in any position on the pillow. This very good effect lasted twenty hours.

CASE 4.—A man, aged 69, suffering for the past 30 years from osteo-arthritis of the lumbar spine. X-ray examination showed very advanced disease, with huge osteophytic spurs. He had the same course of injections, and pain was relieved for eight hours. The next day he had the same injections and this time the result was even better; pain was eased for thirty-six hours.

CASE 5.—A woman, aged 30, suffering from rheumatic fever, under treatment with salicylates. No effect whatever was noticed after the first or the second course of injections.

No toxic effects were noted in any of the 5 cases; nor was there apparently any change in the blood-pressure or in the laboratory findings.

Nicosia, Cyprus. GEORGE J. SPANOPOULOS.

THE CHEST PHYSICIAN

SIR,—The correspondence on the tuberculosis services has continued now for some time, and is serving a very useful purpose in bringing to light the difficulties in this period of change.

It had appeared that the long fight for recognition of the chest physician as a specialist had been won, and that the service could now compete on equal terms with other specialties for the most able consultants. Now, however, it seems that the service dealing with our most urgent health problem is to be handicapped permanently by an inferior status, reflected in a lower scale of remuneration, as the result of separate contracts with the regional board and the local authority. That this would be fatal to future standards in the service is only too obvious.

It is difficult to understand why it was necessary to divide the two aspects of the work. In fact, no division is possible. What is the chest physician supposed to do for the local authority at the proposed lower rate? Is it the examination of contacts, or others, with the object of securing early diagnosis; and is this "clinical" medicine if carried out for the benefit of the individual, and "preventive" medicine when a possible source of infection in the community is in mind? Or is it the promised scheme of B.C.G. vaccination that carries lower remuneration? If so, then skilled clinical work is to be rewarded at one rate by the regional board and at another and much lower rate by the local authority.

Perhaps it is the time spent by the chest physician in investigating the tuberculous patient's social background that is to be paid at this lesser rate. Yet time may have to be spent similarly by the chest physician working in a hospital or sanatorium, and indeed by physicians in other fields, if they take a proper interest in the social aspects of illness. It has not so far been suggested that the principle of the divided contract shall apply to them.

Whatever may have been the origin of this unfortunate suggestion, it should be dropped. At a time when the social aspects of disease are being more clearly understood, it is a most serious error to single out preventive and general care work, in tuberculosis particularly, as an inferior occupation.

Theydon Bois, Essex. HUGH RAMSAY.

THE CONCEPT OF GENETOTROPHIC DISEASE

SIR,—I cannot resist the impulse to comment on the article by Professor Williams and his colleagues in your issue of Feb. 18. The writers claim that a fundamental concept has been recently added to medicine by the study of the genetical basis of biochemical differences. The subject of biochemical genetics is indeed rapidly growing at the present time. Its contact with medicine, however, is of at least fifty years' standing. I find it astonishing, therefore, that the writers, who now propose to add a new name, "genetotrophic," to our overburdened medical vocabulary, appear to be unaware of the work of A. E. Garrod. In an article on alkaptonuria subheaded "a study in chemical individuality," and published in THE LANCET in 1902,[1] he discussed the inherited chemical diversities, which could account for individual reactions to common diseases, as well as those rare chemical specificities whose genetics could be more easily studied. Unlike the nebulous concept of "genetotrophic" disease, Garrod's ideas were clear and really fundamental.

BACTERIAL CONTAMINATION OF AIR IN UNDERGROUND RAILWAYS

SIR,—Your issue of Jan. 21 contained an interesting survey, by Dr. Williams and his colleagues, of the bacterial flora in the air in underground trains.

During the late war some investigations were made on the flora in the throats of shelterers on the four underground platforms at Waterloo station. At the height of the Blitz some 1500 people slept each night on these platforms. In addition, some 80,000 were disgorged daily from the trains; and during the rush hours many thousands picked their way past these shelterers. The latrines were below the sewage level and were supplied with buckets which had to be manhandled to a central point and evacuated by suction-pumps from an open cistern. Every three minutes a train, arriving or leaving, acted as a pair of bellows, sucking the air from every nook and cranny, and spraying it over the occupants.

The authorities, fearing the spread of infectious diseases, had each cot numbered and each shelterer given a corresponding ticket; ticket-holders had to attend the Red Cross hut on the platform, where they were card-indexed and medically examined as regards lungs, throats, and general cleanliness.

The Minister of Health and the medical officer of health visited this centre and suggested that a cross-section of the occupants should have their throats swabbed periodically. Every night two occupants from each platform had their throats swabbed; to make the result as uniform as possible we started alternately from the centre and the ends of the long line of cots. These swabs were collected about midnight each night and taken to St. Mary's Hospital laboratory.

The experiment was discontinued after 52 consecutive weeks (March, 1941, to March, 1942) because the laboratory reported no variation from the flora obtained from the throats of pre-war Londoners.

---

[1] *Lancet*, 1902, ii, 1616.

It was thought at the time that the piston-like action of the trains pushed and pulled the contaminated air through the entire tube system, evacuating it through the air-shafts and so preventing mass accumulation of pathogenic bacteria.

London, W.C.2. J. R. M. COLLIE.

PNEUMOCONIOSIS AFTER EXPOSURE TO SULPHUR DIOXIDE FUMES AND DUST FROM COKE FIRES

SIR,—Dr. Dunner and his colleagues (Feb. 11) have misunderstood the purpose of my letter (Jan. 14) commenting on their article of Dec. 31. I was concerned only to point out that their conclusions should be taken as tentative until more and better evidence is forthcoming. I am glad to see that they have now written to emphasise the same thing. I certainly do not seek to claim that pneumoconiosis could in no circumstances be caused by coke ash; indeed I wrote: "It is, of course, possible that pneumoconiosis can arise in exceptional circumstances." I am not yet convinced that in fact it does occur at all. I am still less convinced that it appears in anything like the proportion of cases they claim.

THE CARNAGE ON THE ROADS

SIR,—I heartily endorse the views expressed by Dr. Learoyd in his article of Feb. 25. The question, it seems to me, is this: who is to start a vigorous national campaign to give effect to these proposals, which, in my opinion, are by no means unduly severe?

Dr. Learoyd contends that the strict training of drivers would halve the death rate; and certainly a large proportion of drivers have never been properly trained, are almost totally ignorant of correct driving procedure, and have never been called upon to undergo the driving test, for what it is worth. Yet often these people do their best to spread their own disability by attempting to teach others, who may not at first pass the driving test but career along with a couple of "L" plates as the only safeguard.

Nobody but a properly qualified driving instructor should ever be allowed to put another new driver on the road; and the candidate for a test should have to produce a certificate showing that he or she has undergone a proper course of instruction.

I would go further than Dr. Learoyd, and propose that every driver ought to be subjected to a driving test every five years, irrespective of his record or qualifications.

FERTILITY AND FAMILY PLANNING

SIR,—In the report on family limitation,[1] prepared for the Royal Commission on Population by the Royal College of Obstetricians and Gynæcologists, it was stated that 23% of all children born to parents who practised birth-control were unplanned. This is a high failure-rate. The experience of family planning clinics is that the "unaccountable" (and possibly inevitable) failure-rate is from 1 to 3%. Medical advice on methods best suited to the individual case and educational propaganda are essential before the recommendation of the Royal Commission, that "public policy should assume and seek to encourage the spread of voluntary parenthood," can be fulfilled.

It is a great pity that the investigation carried out by the Royal College did not cover larger numbers. Only 3120 out of the 13½ million women who married between 1910 and 1947 are included. Even these are not representative since 64% came from London and Glasgow and there was admittedly "a greater proportion of the less well-to-do sections of the population."

In addition to the questionaries on which the report is based, about 7000 were completed from a "maternity" group and general-practice contacts, and other such sources. Had these been included, the survey would have been far more comprehensive, and some valuable data about women in the present child-bearing group would have been obtained.

M. A. PYKE
Hon. Secretary.

SOCIAL SIGNIFICANCE OF SYMPTOMS

SIR,—Dr. Gooddy has done a service in bringing this question to light in his article of Feb. 11. His solution, though it may superficially satisfy some doctors, will not satisfy the patient.

Undoubtedly the inadequate structure of the society in which we live plays a prominent part in the ætiology of many diseases. At one time such illnesses in the wealthy, especially if without organic involvement, formed a remunerative field in medical practice: but in "State" patients they become a nuisance. The National Health Service has given to poorer people a greater chance to bring their symptoms to the doctor; and in many cases the doctor, in caution or desperation, passes the patient on to the hospital clinic. At the same time basic social difficulties are increasing and therefore "social illness" is becoming more rife and also taking up more of the doctor's time. Palliation by voluntary societies, National Assistance, housing priorities, sedatives, and so on, should be regarded as only an emergency measure. In a civilised community the degree of palliation required should be used as an index of the shortcomings of society as a whole.

The "socially" sick are a nuisance to their doctors and their friends, but they come to us for advice and we are in as good a position as anyone to see their difficulties clearly. We would be shrinking from our duty to the individual, who requires to be cured, and to the community, which requires to be protected, if we did not face this problem and advise and assist society, through individuals and organisations, to put itself right.

Kilcot, Glos. AUBREY KAGAN.

ARTERIAL CALCIFICATION

SIR,—Last week's contribution by Sir Adolphe Abrahams should clarify some nebulous ideas about the significance of arterial calcification. He shows that this can occur in the young, be present for many years, and during this time produce no evidence of impaired efficiency. No doubt you will now receive many letters substantiating this by quoting other examples.

I have before me an X-ray film of the pelvis and upper parts of the femora of a young woman who, when the film was taken, was aged 26 and a member of the W.R.N.S. Her complaint was appendicitis and complications and she had no symptoms referable to the legs. In this film the femoral arteries, both superficial and deep, on each side can be clearly seen throughout their courses because they are outlined by a thin layer of radio-opaque material, presumably calcareous. In addition, on the right side the internal iliac, and on the left the internal circumflex arteries are similarly outlined. Wondering what the significance was in such a young person, I have kept this film for some years.

We must be indebted to Sir Adolphe Abrahams for clearly demonstrating that calcification in certain arteries may be present at an early age and have little or no significance over the course of many years.

Surgical Unit, the Royal Infirmary,
Cardiff.
LAMBERT ROGERS.

THE BODY-IMAGE IN NEUROLOGY

SIR,—Dr. Critchley's striking article of Feb. 25 reminds us that the ancients held that the seat of the soul was in the pineal body. This belief may well have arisen through some philosopher's subjective speculations leading to a dissection which disclosed the central and unique organ which corresponds in position with Claparède's "cyclopean eye." The suggestion of a similar belief is embedded in our language in the expression "the mind's eye." But at least one woman, otherwise normal, whom I have questioned on this matter refers the consciousness of her bodily parts to a region not within the skull, but to somewhere in front of the nasal bridge, thus making all her body-image posterior.

As to monsters, a serial ran in the *Berliner Zeitung* some fifteen years ago relating the strange lives of Chang and Eng, the Siamese twins.

By that account, if I remember rightly, they shared little else than their income from exhibiting themselves, their inseparability, and their blood-stream. The latter indeed proved a bone of contention, since Eng was studious and Chang was drunken. Eng therefore suffered the torments of an involuntary intoxication consequent on his brother's excesses, and at last for that cause went to law with Chang. The case was settled by a compromise in which two apartments were furnished in their house, one as a library for Eng and the other as something like a saloon bar for Chang, in each of which they divided their time equally. But, though Eng's blood-stream was still at the mercy of Chang, the latter had a mind and nervous system of his own, which did not learn by Eng's studies; and the latter continued to suffer by his brother's proximity even to death, when the decease of Chang left him irrevocably attached to a corpse, and with the knowledge that where his brother had gone he was shortly to follow.

Wallasey, Cheshire. R. L. WYNNE.

TREATMENT OF TUBERCULOUS MENINGITIS WITH STREPTOMYCIN

SIR,—I read with much interest the excellent article by Dr. Russell and Dr. MacArthur in your issue of Jan. 14.

A relapse took place in seven of their young patients who had been expected to progress satisfactorily. So far as can be judged, Dr. Russell and Dr. MacArthur based a good prognosis in the early stages on clinical observation only. This is often insufficient evidence. I have seen children apparently moribund who in 2–3 days became quite alert; and the temperature can drop immediately. But there was no change in the cerebrospinal fluid (C.S.F.). In none of the cases reported by Russell and MacArthur had the C.S.F. returned to normal; and in three cases the sugar content had been low in successive specimens for some time before relapse.

The question is: is it right to speak about relapse where the child shows clinically favourable response but in the C.S.F. there are the characteristic signs of tuberculous meningitis? We were told by Hinshaw, Feldman, and Pfuetze [1] that exceptionally tuberculous meningitis can be cured in six weeks. But in 4 cases of tuberculous meningitis treated with streptomycin, who died after 16, 32, 45, and 76 days of illness, Péro [2] found a thick exudate over the entire base of the brain. Debré et al.[3] found thick exudate over the base of the brain after 2, 3, 21, and 45 days' treatment. Levinson [4] found that it often took 3–3½ months for the C.S.F. cells to reach normal, and the C.S.F. protein level gradually tapered off to normal in 4–5 months if the patient recovered; so it is perhaps best to avoid the term "relapse" when the child has been treated for less than three months and the C.S.F. is still abnormal.

Most workers hold that if the C.S.F. cells and protein decrease they may expect the child to recover. I have often found that when the child progressed satisfactorily, the C.S.F. in the cells and protein content decreased, while the sugar-level was low showing that the tuberculous meningitis was in the active stage. A low C.S.F. sugar-level may not indicate liability to deteriorate clinically, but it does indicate that the tuberculous meningitis is in the active stage; and the condition may thus respond immediately to streptomycin.

The prognosis in tuberculous meningitis depends on three factors:

1. Improvement of the primary tuberculous complex so that no new spread takes place.
2. Healing of the tuberculous meningitis, shown by clinical investigations and laboratory data.
3. Freedom of the brain from tuberculomata or tuberculous abscess, which often develops during the healing of tuberculous meningitis. The patient can be cured of tuberculous meningitis and die of tuberculosis cerebri.

This last feature is not surprising, because streptomycin cannot penetrate into the brain. However, the streptomycin content of the blood offered to the brain can be augmented. For this reason I have undertaken procaine block of the stellate ganglion; and we want next time to infiltrate with procaine the superior cervical ganglion. We must think more of cerebral tuberculosis if we are to cure tuberculous meningitis more often.

Bródy Children's Hospital, Budapest. BÉLA STEINER.

MECKEL'S DIVERTICULUM

SIR,—Mr. Ward-McQuaid's article of Feb. 25 prompts me to raise the question of when to interfere with a healthy Meckel's diverticulum found *incidentally* in the course of an operation for some other complaint. The following tragedy is perhaps illustrative:

A trooper was admitted to a field surgical unit eleven hours after sustaining a shell wound of abdomen. At laparotomy there was severe general peritonitis from a through-and-through wound of the cæcum. A healthy Meckel's diverticulum was noted, but no action was taken. The cæcum was exteriorised.

He developed an infection of the laparotomy wound. My unit moved forward shortly afterwards, and a follow-up note records that his general condition was excellent 22 days after operation, except for bouts of abdominal colic. On this day he had to be evacuated owing to circumstances beyond anybody's control, and he died in a C.C.S. the next day. Autopsy revealed the Meckel's diverticulum fixed to the left side of the posterior abdominal wall, and coils of small intestine strangulated through the loop thus made—a common enough picture.

Since then I have made a practice of removing a healthy Meckel's diverticulum when general peritonitis is present. Although the resulting suture-line may be liable to adhere to some other structures, there seems less possibility for the formation of a strangulated hernia of small intestine.

Hartley, Plymouth. D. VELLACOTT.

SIR,—Mr. Ward-McQuaid, in his article of Feb. 25, has once again reminded us of the dire consequences which may befall a patient with a Meckel's diverticulum which has undergone pathological change.

He rightly emphasises the importance of examining the last few feet of the ileum when the appendix is found to be normal in a case of suspected appendicitis. I would go further and suggest that the last few feet of ileum should always be examined at laparotomy. It takes but a few seconds to ascertain the presence of a Meckel's diverticulum, and a decision to remove it may be taken. It has always been my practice to make this examination and to remove the diverticulum, provided that the main operation has not been one of extreme severity and that

the patient's condition will permit of a little extra operating-time. This surely is as sound a practice as routine removal of the appendix, for neither structure is a respecter of age or person. It is not uncommon to find a band running from the apex of the diverticulum to some other part of the abdominal cavity; and even if the diverticulum is not removed this band can be quickly divided and a dangerous source of intestinal obstruction removed. General peritonitis from a perforated Meckel's diverticulum has, in my experience, been an extremely lethal complication, since the "walling off" is flimsy, and the peritoneal cavity is rapidly infected with the contents of the small gut.

My old chief, the late Cecil Joll, always looked for a Meckel's diverticulum at laparotomy. He often quoted the case of a colleague's son upon whom he operated for acute appendicitis. He found not only an inflamed appendix but also an inflamed Meckel's diverticulum.

The removal is not difficult, provided that narrowing of the lumen of the ileum is avoided by repair of the bowel-wall in its transverse axis. Resection of a length of ileum is rarely necessary—a fact which may comfort the "occasional" surgeon who has to perform emergency laparotomies.

TUBERCULOUS MENINGITIS IN CHILDREN

SIR,—Dr. MacCarthy and Dr. Mann state in their important article of Feb. 25 that the relapse of one of their cases was likely to have been precipitated by a pneumo-encephalogram which had been done ten days previously. Of their 43 cases, 20 are stated to have shown no initial response to treatment and all died. Of the remaining 23 recrudescence or relapse of the infection occurred in 12—over half the cases. In only 1 of these did pneumo-encephalography precede the relapse; and therefore it is more than doubtful whether it had anything to do with it, especially as the intervening period was rather long. It is impossible to prove that this relapse would have occurred without this intervention, but it seems reasonable to suppose that it could easily have happened, in view of the high relapse-rate in their series.

In my experience of over sixty pneumo-encephalograms and ventriculograms in tuberculous meningitis I have not yet seen a relapse as a result of this procedure.

Department of Child Health,
University of Sheffield.

JOHN LORBER
Research Assistant.

SIR,—Dr. MacCarthy and Dr. Mann are to be congratulated on the comprehensive account (Feb. 25) of their cases of tuberculous meningitis in children. We are particularly interested in the cerebrospinal fluid (C.S.F.) findings, and would like to comment on the fact that the C.S.F. chloride is not once mentioned. We have found chloride estimations helpful in prognosis, though this experience does not accord with that of others.

From a smaller series of cases, some of whom are still under active treatment, it has been noted that: (1) no case has died with the C.S.F. chloride above 660 mg. per 100 ml.; (2) every survivor, after initial fluctuations during the first two months of intrathecal streptomycin treatment, has shown a gradual but steady rise in chloride content towards, and beyond, 700 mg. per 100 ml.

One patient during the last eighteen months has four times been treated and discharged clinically well, and has then suffered a recrudescence; and she is now undergoing a fifth course of treatment. On the four occasions of discharge the C.S.F. chloride was 583 mg., 625 mg., 550 mg., and 710 mg. per 100 ml. In the present state of our knowledge, these values suggest that she should not have been discharged on any of these occasions, because on the first three the chloride was well below 700 mg. per 100 ml., and on the last this value was only just attained.

Furthermore, the C.S.F. chloride value is not significantly affected by slight delay in making the estimation; and the result is more accurate than that from estimation of glucose content, which may be misleading if delayed more than ten minutes after withdrawal of the fluid.

In our experience estimation of C.S.F. chloride has been of some prognostic value in cases of tuberculous meningitis treated with streptomycin.

RHEUMATIC FEVER AND MILK

SIR,—In an interesting article on Diet and Disease in the Subarctic, Duncan[1] refers to the absence of rheumatic fever in a semi-closed community in the Yukon. For fourteen years, he says, he tried to find a typical case, but without success, although there were at least 350 children under fourteen years of age in his care during this time. His statement is of particular interest in view of the fact that the ætiology of rheumatic fever is still a puzzle. There is a considerable amount of evidence that the disease is a manifestation of allergic hypersensitivity to the streptococcus or its products, and I would like to draw attention to some further evidence in support of this claim.

We know that the original sensitising dose of antigen, in any allergic disease, need only be minute, and that in the experimental animal 0·000001 ml. is sufficient to produce the anaphylactic state.[2] If we include rheumatic fever in the allergic category, a small original dose of streptococcal antigen will be enough to induce the state of sensitisation which is, presumably, a prerequisite of the disease. We know also that in infancy the ability of the gut to absorb foreign protein—e.g., B.C.G. vaccine —is high. *The possibility of sensitisation to the streptococcus* being produced in infancy from occasional doses of streptococci or their products in the feeds should therefore be remembered. Such doses may occur in cow's milk. Gunnison et al.[3] examined a series of milk samples and obtained strains that were potentially dangerous to man, though only from less than 1% of the samples. If supplies are bulked, however, the distribution of potentially dangerous milk will be wide. An official leaflet[4] points out this possibility. It states that milk from cows infected with mastitis should never be mixed with the bulk of clean milk, but as most cases are subclinical a considerable amount of such milk is, in practice, inevitably present in the bulk. It is possible that the streptococcus responsible for this condition has antigenic properties in man, but, whether this is so or not, it has been found that human strains of streptococci can infect the udder.[5] With this in mind I inquired of Dr. Duncan as to the extent to which raw milk was used as an infant food in his community. His reply was as follows:

> "Practically all the milk used in this country is of the canned condensed variety. There is some powdered milk used, but it is not as convenient as the canned type. There is only one small dairy in the Yukon and it sells a small amount of raw milk to Dawson. I don't allow my patients to feed it to the local babies."

This answer, then, provides a possible clue to the ætiology of rheumatic fever. It is a clue which harmonises with many of the known epidemiological features of the disease. Geographically it is confined mostly to temperate climates, being rare in the tropics, where fresh milk must be boiled in order to improve its keeping qualities, and in subarctic regions, where it is not widely available.

If the hypothesis suggested is well founded, the practice and maintenance of breast-feeding of infants or, alternatively, the use of dried-milk preparations or sterilised liquid milk in infant feeding would constitute an important preventive measure. In addition to the Yukon, two other semi-closed communities which enjoy relative freedom from the disease will be mentioned, and in both the incidence of breast-feeding is high. The first consists of two districts in Shetland; the second is Iceland.

The medical officer of health for Shetland, who has records extending over several years, states that a comparison of his statistics with those relating to places on the mainland of Scotland or England leads him to conclude that breast-feeding is more widely practised in his area than elsewhere.[6] In two districts—namely, Burra Isles and Unst—which, it will be shown, have a low incidence of rheumatic fever, the percentage of infants wholly breast-fed at three months was about 64. The corresponding figure for the mainland has been variously stated. In a mining community it was below 41 [7]; for England and Wales generally, about 50 [8]; while in Scotland, according to an official report, "it does not at once appear that the incidence of breast-feeding is less, or that lactation is less well maintained, than in England," and for some well-to-do communities high rates are quoted.[9] But Shetland differs from the mainland in one important respect. Cow's milk was never widely used when bottle-feeding was resorted to, because in many places it was not available. This is illustrated in the Burra Isles, where, at December, 1948, according to the records of the local food office, permits for tinned milk in lieu of fresh milk were in force on behalf of 149 households out of a total of 170. And here rheumatic fever is uncommon. The medical practitioner has seen only 4 cases in twelve years.[10] With an estimated population during this time of 725, the incidence is found to be 0·46 per 1000. The incidence for Scotland as a whole, calculated from the crude death-rate for rheumatic fever and the general mortality-rate given by Glover,[11] is 4·5 per 1000. On the island of Unst the practitioner has seen not more than a dozen cases in the whole course of his fifty years in practice there.[12] This gives the phenomenally low incidence of 0·12 per 1000, taking the average population during the period as 2000.

The other example of the association of high breast-feeding rate with low incidence of rheumatic fever is Iceland. In Reykjavik, with a population of just over 37,000, 97% of the infants are wholly breast-fed when the midwife leaves, and "until recent years all infants were breast-fed 6 to 10 months." [13] For the island as a whole (population 114,000) the corresponding percentage is 90.[14] Strand,[15] who collated his own estimates with those of three general practitioners, states that at three months 60–65% of infants in the towns and 75–80% in the country are breast-fed. Of the rarity of rheumatic fever in Iceland there seems to be no doubt. There were only 9 deaths from it in the decennium 1929–38—a crude rate of only 0·8 per 100,000, as opposed to 4·5 per 100,000 in Scotland. In the same decennium, 1533 cases were notified. The mortality-rate accordingly is 0·59 per 100 cases—a low value which confirms the observations made by a correspondent [16] in THE LANCET that the disease in Iceland is of a mild type. The incidence is also low, the rate from these figures being 1·34 per 1000 of the population.

It may be objected that, because the incidence of breast-feeding in the United Kingdom has been declining, rheumatic fever should, by this hypothesis, have tended to rise in recent years—which it has not done. Several points go far to meet this objection—namely, the improving standard of milk quality, the growing practice of boiling milk which is being prepared for the feeding-bottle, the use of dried milk as baby-food, and, finally, pasteurisation. If the pasteurisation of milk reduces the incidence of rheumatic fever—and some milk-borne streptococci are known to be destroyed by this measure—then mortality from rheumatic heart-disease will fall in those areas where it is widely employed. The administrative county of London is such an area. In 1939 nearly 93% of the milk was pasteurised under licence, and over 98% was heat-treated in some way or other. In the rural districts of England and Wales probably only a small proportion of the milk was pasteurised in 1939. This situation was reflected in the death-rates from non-respiratory tuberculosis.[17] It is known that a proportion of deaths from this cause are the result of milk-borne infection and that the danger of this infection is removed by adquate pasteurisation or other form of heat treatment of the milk. Wilson [17] has shown that the fall between 1911 and 1937 in the 0–4 and 5–14 age-groups has been far greater in London than in the rural districts, though during these years the respiratory-tuberculosis death-rate fell to almost the same extent in the rural districts as in London. There are grounds for believing that mortality from rheumatic fever behaved in the same way. It cannot be directly investigated, but there are good reasons for adopting as a measure of its extent the 5–14 age-group death-rates from heart-disease.[18] This rate fell 63% in London, while in the rural districts the fall amounted to only 32%, as is shown by the following figures for the death-rate from this cause per million persons aged 5–14:

	1911		*1937*
London administrative county	281	..	103
Aggregate rural districts..	91	..	62

Knowelden [18] showed that between the years 1920–22 and 1936–38 in both the 5–14 and the 15–24 age-groups the death-rates from heart-disease for both males and females fell much more in London than in the rural districts. He called it a curious local phenomenon with no obvious explanation. The present hypothesis, however, supplies one. Further study of the geographical distribution of rheumatic heart-disease and non-respiratory tuberculosis both in this country and in the U.S.A., provides additional support for such a view.

Milk-borne streptococcal outbreaks have frequently been recorded. Occasionally these have been followed by outcrops of rheumatic fever. It may be that a milk-borne allergen is a fundamental factor in the ætiology of the disease, and if so, withholding of raw milk from the diet during treatment will have a favourable effect. This is a practicable line of further inquiry, and I hope sufficient interest will have been aroused to encourage someone to adopt it.

I am grateful to Mr. Daniel Lamont, Gilbert Bain Hospital, Lerwick, for issuing the questionnaire, and to the medical practitioners for coöperating; to Dr. S. A. B. Black, medical officer of health, Shetland, Dr. A. C. Duncan, Yukon, Dr. K. Strand, London, and Dr. Brian Roberts, Cambridge, for relevant information; and to Prof. C. H. Browning and several colleagues in the Department of Health for Scotland, for guidance in the presentation of this material.

"SUFFOCATION" IN INFANCY

SIR,—Leading articles by THE LANCET have come to achieve the weight of legal pronouncements, for they usually have the strength of authority and reason—and are well informed. But the article in your issue of Feb. 25 is wholly illogical and grossly misleading. It has caused no small disquiet among forensic pathologists and it is not far short of libellous to coroners.

F. B. Smith, whose sound arguments it so misrepresents, pleads for honesty at autopsy and for recourse to the laboratory when in doubt. He suggests "unknown" as "preferable" to guessing, not "more accurate," and he certainly did not suggest that coroners "are usually interested only in the legal aspects" of infant deaths from suspected suffocation. Coroners have a duty to ascertain the facts, and there is no limit to the trouble or expense they may entertain to achieve this end. It is quite untrue to say that "necropsy is seldom ordered, and the doctor's opinion of the cause of death is accepted"—not true, that is, except in some rural districts where advance is slow. It is certainly not true in London, where every such case is subject to the revealing light of autopsy and laboratory test where desirable.

To caution the doctor against a casual acceptance of suffocation in infants found asphyxiated in bed, as I[1] and others have, is apparently to convince some that suffocation must be suspect, not suspected. This is an elementary illogicism, and Smith has not made it, as your article asserts.

Children found dead on their faces *may* have suffocated; let us ascertain the real truth, as Smith says, by every means at our command without bias, and we shall then have facts which *might* enable THE LANCET to say that 40% of such children are, in fact, undoubtedly suffocated—not that "most of the infants supposed to have died from accidental suffocation really died from natural causes." This is a bare majority and it is grossly misleading to quote it so; it would be fairer to say that coroners are anxious to ascertain the truth of this everyday disaster, willing to cooperate with the pathologist in his efforts to do so, and cognisant with him of the established fact that about a half *are* suffocated and a half are not. The rough truth is better than dangerous misrepresentation.

Guy's Hospital, London, S.E.1. KEITH SIMPSON.

*** Our remark about coroners was not quoted from F. B. Smith: it was a paraphrase of W. H. Davison's comment that "as over 70% of coroners have no medical qualifications their interest is mainly confined to the purely legal aspect of each case" (*Brit. med J.* 1945, ii, 251). We gladly accept Dr. Keith Simpson's assurance that, where suffocation is suspected, post-mortem examination is nowadays ordered more than "seldom." It is true that, of the 233 cases of asphyxia in infants covered by Dr. Simpson's survey, 93 (40%) were attributed to suffocation (*Lancet*, 1947, ii, 745); but in view of the lower figures of other observers we doubt whether his rough truth that "about half *are* suffocated" is any less rough than our own statement that "it seems probable that most of the infants supposed to have died from accidental suffocation really died from natural causes."—ED. L.

FÆCAL UROBILINOGEN IN SULPHONE THERAPY

SIR,—In his article of Jan. 28, Dr. Lowe wrote: "The Schlesinger test for urobilin in the urine is useful in cases of suspected toxicity, for the test with Ehrlich's reagent does not work when sulphones are present in the urine." We have had the same experience with 'Sulphetrone' and would like to add some observations on the determination of fæcal urobilinogen in the presence of this drug.

During the treatment of tuberculous patients with sulphetrone at St. Andrew's Hospital, London, E.3, routine analyses of fæcal urobilinogen were carried out in an attempt to assess the degree of hæmolytic anæmia caused by the drug; we were working on the arbitrary assumption that sulphetrone did not inhibit the bacterial synthesis of urobilinogen.

Ehrlich's quantitative *p*-dimethylaminobenzaldehyde reagent was used according to Maclagan's[1] procedure. As distinct from the usual practice, it was found necessary in these cases to read the colour intensity in a photo-electric colorimeter immediately after mixing with saturated sodium-acetate solution. The colour faded rapidly, reaching about a third of its original intensity within 10 sec. The reaction between urobilinogen and the aldehyde proceeded normally before the addition of sodium acetate, and the reaction-time of 10 min. was found to be essential for full colour development.

To ascertain whether fading was due to the presence of sulphetrone or of a metabolic product, the urobilinogen content of normal fæces was determined with and without the addition of the drug (using 9 ml. of a solution containing 100 mg. per 100 ml. to triturate 1·5 g. fæces). The normal test solution contained 76 mg. urobilinogen per 100 g.; that containing added sulphetrone had 79 mg. per 100 g. on immediate reading, followed by rapid fading. Similar experiments adding sulphanilamide, sulphadiazine, and succinylsulphathiazole in the same concentrations showed no interference with normal urobilinogen estimations.

In the stage preceding the addition of sodium acetate, the strongly acid solution should contain the drug in the free diaminodiphenyl sulphone form. This does not seem to prevent the interaction of urobilinogen and the aldehyde reagent. Subsequent interference by the sulphone may be due to the formation of an azomethine (possibly the known N-(*p*-dimethylaminobenzylidine)-*p,p*-sulphonyldianiline[2]) which would be unstable in strong acid but stable in a weakly acid acetate buffer.

The trial of sulphetrone in tuberculosis was later discontinued, and this subject was not pursued. No publication of these findings was intended until it appeared that they might be of use to workers in the leprosy field.

A. L. TÁRNOKY

London, E.3. V. ANNE L. BREWS.

PERSONALITY AND NURSING

SIR,—It is always unwise to be too optimistic about the results of an experiment until it is completed, particularly when the data are inadequate. In their article of Feb. 25, Mrs. Petrie and Miss Powell suggest that their battery of tests should be used for the selection of candidates for nursing; but the preliminary tests, as stated in the summary, were done on student nurses who had already done over six months' training. The "switch-over" from students to candidates can only be justified if it can be assumed that six months' training as a nurse—for example, at 19 years of age—has no effect on personality test scores. Such an assumption is probably not correct, although it may be.

The deduction that the use of tests would enormously reduce the number of unsatisfactory nurses is unwarranted. The tests were applied to those who had already been selected, to pick out the best three-quarters, since a quarter are unsatisfactory. To compensate for the elimination of these, the original interviews will have to pass about 10% more candidates. Now if the interviews have any effect at all, it is clear that, as a greater proportion of candidates is passed, the quality of the additions will tend to fall. The best 10% are included in the best 20%, which are included in the best 30%, and so on. The essential point is that it is invalid to argue from a sample group to the population from which it has been selected, until the basis of selection is known and the efficiency with which it has been carried out. For those not statistically minded, an example will make this clearer.

We will consider the two extreme situations, and assume for the moment that the selection committee is perfect.

---

[1] *Lancet*, 1947, ii, 745.

[1] Maclagan, N. F. *Brit. J. exp. Path.* 1946, 27, 190.

[2] Jain, B. C., Mirchandani, P., Iyer, B. H., Guha, P. C. *Science and Culture*, 1946, 11, 567. See also Freedlander, B. L., French, F. A. *Amer. Rev. Tuberc.* 1947, 56, 360.

This implies that only $22^{1}/_{2}$% of the candidates will make good nurses. The committee selects this $22^{1}/_{2}$% plus another $7^{1}/_{2}$% to make up the 30% of acceptances. Of those selected, a quarter will not make good nurses. In such a case, the use of the tests will not make any difference to the final results, assuming that the tests are going to pick out the good three-quarters. Now let us assume that the selection committee has zero efficiency, so that its efforts are equivalent to picking names out of a hat. This implies that 75% of the candidates will make good nurses. The committee selects 40% of the candidates and the tests then pick out the good three-quarters. In this case, all failures will be eliminated, and the tests do all the work. It is reasonable to assume that the present situation lies between these two extremes, but until the exact state of affairs is known it is impossible to estimate what the tests will do.

Both of these points are of minor importance in comparison with the next. The investigation is essentially one concerned with prediction: is it possible to predict, by means of tests, which candidates will make good nurses? The only way to find out is to use the tests for prediction. Apparently this has not been done. It can be demonstrated on theoretical grounds that the correlation between obtained results and predicted results is much less in a check sample than in the original sample, when the best tests are selected according to the data of the original sample. "No matter how well the criterion and the weighted prediction scores correlate for the sample, this correlation will tend to drop materially on successive samples."[1] Actual experience confirms this.[2–4] A multiple correlation of 0·6 may seem very high, but the figure is likely to be only 0·3 when the tests are applied to the next batch. If so, it will not be of great value for individual prediction.

It is not my intention to decry the value of scientifically validated tests against the amateur selections of untrained interviewers. A very strong case could be made that most interviewers do not know what they are selecting and why—i.e., they are unable to define the characters they are looking for, or the relation these characters have to the demands of the job. On the other hand, the use of tests in this country is very new, and one that is still greeted with some suspicion. It will only be a hindrance to the development of scientific methods of selection if enthusiastic supporters make exaggerated claims for them; for such claims are bound to fall short of the facts when they are finally put to the test. The old methods will be continued, and social waste and individual disappointment will remain undiminished.

Public Health

Arsenic in Food

IN a report issued last week the metallic contamination subcommittee of the Food Standards Committee recommends amendment of the standards laid down in 1903 by the Royal Commission on Arsenic. The Royal Commission's recommendations have never been given statutory force (except that in the Edible Gelatin Order, 1948, the Ministry of Food prescribed a limit of 1·4 parts per million [p.p.m.] arsenious oxide in edible gelatin equivalent to gr. $^{1}/_{100}$ per lb.); but the Commission's findings have served as standards in commercial practice and have been accepted as recognised limits in the Courts. The limits adopted by the Royal Commission was gr. $^{1}/_{100}$ per lb. (1·4 p.p.m.) of arsenious oxide for solid foods, and gr. $^{1}/_{100}$ per gallon (0·14 p.p.m.) for liquid foods.

The subcommittee proposes that arsenic contamination should be expressed in terms of the element arsenic (As) and not, as hitherto, in terms of arsenious oxide (As_2O_3); and the arsenic content should be expressed, as with other trace elements, in terms of parts per million.

Water and milk should not, says the report, contain arsenic; but if inadvertently arsenic has gained access to either, it should not be consumed if the arsenic content is more than 0·1 p.p.m. The following limits for arsenical contamination should, it is proposed, be prescribed statutorily:

Beverages, ready-to-drink, 0·1 p.p.m. As (0·14 p.p.m. As_2O_3)
Foods not otherwise specified, 1 p.p.m. As (1·4 p.p.m. As_2O_3).
Foods in a schedule as follows:

	p.p.m.	
	As	*As_2O_3*
Food colourings containing more than 10% of colouring matter	5·0	6·6
Beverage base:		
Total solids up to 35%	0·1	0·14
,, ,, between 36% and 69% ..	0·5	0·7
,, ,, over 70%	1·0	1·4
Edible gelatin	2·0	2·7
Dried herbs, spices, dried liquorice extract ..	5·0	6·6
Dehydrated onions, phosphatic constituents of raising powders, hops and hop concentrate	2·0	2·7

The report suggests that the sale of fresh or processed fish, sea-fish, crustacea, and shell-fish containing arsenic in excess of 1·0 p.p.m. shall not be forbidden provided that such arsenic is natural to the fish.

Fluorine Investigation in Children

Last week the Ministry of Education announced that over 3000 school-children in various parts of England are to take part in a test of the effectiveness of fluoride applied locally to the teeth to prevent caries. The following bodies are participating:

Eastman Dental Clinic with the L.C.C.);
Newcastle Dental Hospi ation authority;
Leeds local education local education
authority; Sheffield D local education
authority; Birmingham Dental Hospital; Bristol local education
authority; and, possibly Middlesex local education authority.

No child will be included in the investigation without the parents' consent. The teeth of the children who are included will be examined annually.

Third Quarter of 1949 in Eire

A report[1] on the third quarter of 1949 in Eire shows that the birth-rate was 22·1 per 1000 of the population. Deaths were at the rate of 10·8 per 1000 per annum. The death-rate from all forms of tuberculosis was 0·8 per 1000 (pulmonary 0·6, all other forms 0·2); the corresponding rates for the third quarter of 1948 were 0·9 (0·7, 0·2). The infant-mortality rate was 44 per 1000 births registered, compared with 38 in the same quarter of 1948. The population at the middle of the year 1949 is estimated at 2,991,000 (1,513,000 males and 1,478,000 females).

Obituary

JOHN ALFRED RYLE

M.A. OXFD. M.A., HON. M.D. CAMB., M.D. LOND., HON. D.SC. MCGILL, F.R.C.P.

We have already announced, with deep regret, the death of Prof. John Ryle at his home in Sussex on Feb. 27 at the age of 60. The talents that made him one of the finest clinicians of his time were devoted in his last years to social medicine, in which he attained a world-wide influence. In searching for new techniques and in trying to promote a change of attitude among doctors he encountered the trials of the pioneer; but he achieved much, and his influence will continue.

Son of the late R. J. Ryle, M.D., of Brighton, and grandson of Bishop Ryle, he was educated at Brighton College and at Guy's Hospital, where he was awarded the London University gold medal in medicine and qualified in 1913. From resident appointments at Guy's he went to the war and served with the R.A.M.C. in Belgium and France from 1914 to 1918. Returning to his hospital on demobilisation, he became assistant physician in 1920 and demonstrator in morbid anatomy and medical pathology. The period which followed was one of fruitful investigation, in which Ryle's balanced judgment found a fitting complement in the enthusiasm of Arthur Hurst, both at Guy's and at New Lodge Clinic. His Goulstonian lectures to the Royal College of Physicians in 1925 dealt with Gastric Function in Disease, and he became known for his work on the gastro-intestinal tract; but his studies of cardiovascular disorders are scarcely less valuable. He had been brought up in a school which taught that the way to learn the art of healing was by careful note-taking at the bedside and by a detailed clinical examination of the patient. It was natural that he should become interested in the meaning of symptoms, and he contributed valuable papers on such clinical phenomena as heartburn, "acidity," anorexia nervosa, and spasm of the colon. In his search for the explanation of such symptoms he had perfected (with Izod Bennett) the method of fractional test-meal analysis, and the "Ryle's tube" which formed the means of taking gastric samples is known the world over.

Ryle's wide range and his interest in people made him outstanding as a consultant in difficult cases. But he was also outstanding as a teacher of elementary clinical medicine. He was not spectacular, and never attempted to be a showman; but he brought knowledge and sense to bear on everything he touched. It is a great asset for a teacher to be also a clear thinker, for then he can impart his knowledge to others to the best advantage: possessed of a pleasing voice, which was never raised even in admonition of a careless clinical case-record, he made a deep impression on those he taught.

> "To my generation of Guy's men," writes a former student, "Ryle was supreme. His teaching was exemplary, though at first we did not realise the effort that it cost him. His opinion that 'full notes, frequently perused, are the essence of clinical education,' coupled with his dictum that 'teaching must be fertilised by research,' explains much of his success. He knew all his ward clerks and delivered his message t them, realising that 'postgraduates' wanted differen teaching. His clinical lectures were a stimulus and a joy his perfect diction and choice of words enhanced the unfoldin of a difficult problem. In the post-mortem room his knowledg of morbid anatomy made him a pathologist true to hi school."

It was not only the subject matter of his teaching which will be remembered, but also the method of hi approach to patients; he gave confidence to every patien to whom he ministered, and was adored by many Such was his success that his consulting practice becam larger and more exigent than his physique could bear. The only way to circumvent the limitations it imposed was to leave London, and in 1935, at the age of only 46, he accepted the regius chair of physic at Cambridge. His academic fitness for such a post was shown by his collected lectures and essays appearing in the following year under the title *Th Natural History of Disease*, and it was hoped that he would create at Cambridge a new school of clinical investigation. The early establishment of a university department of medicine, whose members should work closely with Addenbrooke's Hospital, gave high hopes of a flourishing centre of research and teaching. Yet, sad to say, the dream faded as Ryle's enthusiasm met the delays and pinpricks inseparable from the introduction of a new venture into an academic system suspicious of sudden change. The pace was too slow, and it seemed that perhaps he took this too much to heart. Finally in 1939 the war broke up his cherished department: he went back to Guy's, and to work for the E.M.S. and Ministry of Health, and Cambridge saw him less and less. But those who had the privilege of working with him retain the memory not only of a great clinician but also of a transparently honest idealist and of a chief whose friendship and encouragement were invaluable.

His war activities, including a survey in the north-east, and his brave return to Guy's during the time of devastation, told heavily on Ryle's constitution; and it was in this dark period that he turned his thoughts to the problems of fear and pain, of life and death. His book of essays, published in 1941 under the title of *Fears may be Liars*, was directed primarily towards those who were exposed to the stress and sorrows of ruthless war; but they were more widely drawn to include all who suffer in the actuality of pain or the anticipation of death. His philosophy contains no element of escape; the physician is comforter and he instils a brave belief in death. As we put it at the time:

> "Between the purely materialist and devoutly religious philosophies, Ryle stands intermediate, as a naturalist and humanist. For him, man has an allotted task to fulfil—that of using his gifts of body and mind to the utmost and the best of which they are capable. Ryle finds implicit in nature and human society a principle of mutual aid, which should be an important ingredient of effective living, and should teach modern science that it has social and moral as well as academic functions."

In these essays also he begins to lay more emphasis on the scientist's duty to the community, to give expert guidance in the preventive field. Instruction in the art of living healthily, he says, must become a more important concern than that of discovering new treatments for preventable diseases.

In 1943 Ryle was appointed Nuffield professor of social medicine at Oxford. The chair itself represented in a very real sense the fruition of his own experience in London and of the ideas which matured during his professorship in Cambridge: he had transferred his energies—to use his own words—from work in the field of clinical and personal medicine to new ventures in the field of social medicine—from studies (in a more academic regard) in individual pathology to studies in social pathology. After five years of work in Oxford he was able to write, with his characteristic sincerity:

> "Some of my friends have rebuked me for leaving the clinical fold. I reply in effect that I have merely taken the necessary steps to enlarge my field of vision and to increase my opportunities of ætiological study. My allegiance to human medicine is in no whit broken. I wish I could convey to them and to others some of the sense of stimulation and rejuvenation that my close association with statisticians and medical social workers and with men and women in the public health and industrial health services has brought to me. Thirty years of my life have been spent as a student and teacher of clinical medicine. In these thirty years I have watched disease in the ward being studied more and more thoroughly—if not always more thoughtfully—through the high power of the microscope; disease in man being investigated by more and more elaborate techniques and, on the whole, more and more mechanically. . . . With ætiology—the first essential for prevention—and with prevention itself the majority of physicians and surgeons have curiously little concern." (*Changing Disciplines.* London, 1948.)

It will be seen here that Ryle is still a pathologist, but his deepest interest is in the *social* post-mortem examination and the science of causes. Indeed his book, the first (and unhappily the last) of his gathering, is described as "lectures on the history, method, and motives of social pathology." He used to say that social medicine had increased rather than diminished his love of clinical medicine. He had witnessed in his time at Guy's great changes in the symptomatology of rheumatic fever: at Oxford he tried to elucidate its social pathology. Peptic ulcer, with all its complications, was perhaps the disease for which he was consulted more than anything else: in his *Changing Disciplines* he leads us to consider whether gastric and duodenal ulcers are different entities, with nervous trauma as the more dominant factor in duodenal ulcer and mucosal trauma in gastric ulcer. He had been one of the few general physicians who thoroughly understood the clinical picture of angina pectoris and coronary disease, and one of his last publications was a statistical paper based on the Registrar-General's statistics and his own experience of the increasing incidence of coronary disease. He had keen vision of the human side of all problems: he knew what lay behind a graph.

It is difficult for men who knew Ryle well to speak dispassionately of his personality and character. He could not have been such a success in practice without a great understanding of people, even if his own high standards left him less familiar with some of their frailties. To many who knew him he never seemed quite so much at home in writing of patients in the mass—in his last appointment as professor of social medicine—as when writing about the individuals for whom he cared so much. But if he could not easily be replaced as a consultant, and if he ceased to instruct hospital students directly, he remained a teacher; and his last six years displayed a remarkable capacity for leadership, while his travels abroad showed his young and eager spirit. Conscientious to a fault himself, he did not willingly lay burdens on others; yet he was often an outspoken critic when he felt there was an error to be set right or slovenly thinking to be corrected. He had the reputation of being somewhat olympian and aloof; but his interest in simple things and in the ways of nature prevented him from becoming formidable to the young, with whom he had an unforced sympathy. Even at Oxford, his life was very far from smooth: he had thought out what might be done by a new approach to medicine, but he did not yet know *how* to do it, any more than anyone else; and he was therefore an easy target for criticism. He had one amiable weakness—all his geese were swans. But the reverse side of this was that in his own department he got the best out of everyone. All knew that he would never tolerate a quarrel on small issues but was prepared to go to the stake on big ones.

Despite disappointments, he had in the end a sense of fulfilment: in a letter to a friend written only a few weeks before his death he said:

> "I have had such a varied, interesting, and happy innings in Medicine during the 37 years since qualification that I should be churlish to complain. In a measure the last six and a half years have been among the most satisfying of all, in that I have been helping to create and reorientate; and to build a bridge . . . between the more strictly clinical and the more broadly social components of Medicine as a whole."

This happiness was enhanced by the peace and serenity of his home, and by the books and the birds which were all about him.

We conclude by printing two personal notes from colleagues at the Institute of Social Medicine which he founded.

* * *

I only came to know Professor Ryle personally after he came to Oxford in 1942. Before that I used to wonder why he had such a remarkable reputation amongst the people whom he had taught and worked with, which seemed to me to amount almost to idolatry. Something much more than could be accounted for by the fact that he was generally recognised as being in the top flight of clinicians and teachers of medicine.

After he had been in Oxford three years, he asked me if I would join the staff of the Institute of Social Medicine because he knew that I was interested in the research aspects of industrial medicine and had some experience of survey work. At the time I had no clear idea of what was meant by social medicine and I had a sneaking feeling that if I went into the department I should have to give up medicine for almoning. But I had already learnt from my experiences in South Wales and the Midlands, that there was far more interesting medicine outside a hospital than ever came into it. After some hesitation, therefore, I agreed to come. Looking back, I realise that I was already under the influence of Professor Ryle's personal magnetism.

I soon found that I need have no fears about social medicine not being sufficiently academic, and quickly learnt that my rudimentary training in logic, mathematics, and sociology was quite inadequate to cope with this new subject, which was far more than "a series of follow-up studies of patients after leaving hospital" and turned out to be a study in the development of techniques for identifying the pattern of disease in the community ("social pathology"), which requires the stern discipline of statistics and a knowledge of many things that never come the way of a practising doctor.

We have all been learning the hard way. But I have never enjoyed working with anyone as much as I enjoyed working with Ryle, and much as I used to love clinical medicine nothing would induce me to return to it. (I too have joined the band of idolaters!)

The complete absence of any sense of friction between different groups of workers struck me as soon as I entered the department, and I soon learnt that it all came from the top. I suppose we were all subconsciously aware of Ryle's integrity and singleness of purpose, and knew that he had given up position, money, and even reputation to devote the last years of his life to what he was trying to do.

Professor Ryle may have been 60 years old when he died, but if age was measured by mental eagerness, he died very young. He was learning right up to the last moment and was always prepared to put himself into the position of an ignorant student anxious to sit at the feet of the learned. It was almost naive the way he would tell us what he had learnt from dipping into the Registrar-General's statistics and would ask us whether we could explain some simple statistical point. He never interfered with the day-to-day work of the different sections of the department, but we always knew that he was there to turn to for advice, and that he would never allow a thing to start unless he appreciated the purpose for which it was designed and had decided that there was a reasonable possibility of the objective being achieved.

A. S.

When I came to Oxford to start the Nuffield Bureau of Health and Sickness Records, the Institute of Social Medicine consisted of John A. Ryle, W. T. Russell, and a secretary. It was in the long vacation and Ryle was down in Sussex. I had his room for a month, one day he walked in, tall, bronzed, smiling. I can see that smile now and I remember how delighted I was to meet a man who was honestly glad to make a new acquaintance. Many hundreds of visitors to Oxford have seen that welcoming smile, and have been made to feel as I did. During the past seven years, people from every part of the world visited Ryle at 10, Parks Road. Most of them were still writing to him for help and encouragement long after he was unable to give it to them.

For years I used to explain to him that if he wanted to talk to me all he had to do was to ring a bell and I would come down to his room. For years he walked up the stairs to my room, and smiled when I expostulated. I tried to persuade him to use an "intercom," but he thought it an impersonal way of talking to people and went on walking in search of those he wished to chat with. It was the same with visitors: Ryle's standard of courtesy demanded that he walk round with them, introducing them to "the colleagues" (he never spoke of his "assistants" or his "staff") and making sure that they got the information for which they had come. He had an arrangement with his secretary for an "exhibit" of the institute's various projects to be assembled at a few minutes' notice (it was a collection of charts, forms, statistical tables, and photographs) so that he could demonstrate his points more easily. I have seen him take the same pains to explain his exhibit to a preclinical medical student as he did for a visiting Minister.

All the junior staff loved him. He would walk round the building on Christmas Eve, or on the eve of any holiday, or before he left on a trip abroad, and talk to everyone. When he came back, he went round again. But when we did anything which showed that we liked him he was surprised. Once someone had the idea of sending fresh flowers to his flat to greet him on his return from the U.S.A. He was quite moved.

Everyone, at some time or other, was asked round to the flat. He would talk about anything and everything, but sooner or later the talk came round to birds, flowers, nature. One year, I remember, his concern was all for a family of kestrel hawks down in Sussex. Natural history, archæology, philosophy, he talked well and compellingly on these and other topics. The conversation would rapidly shift to one of these whenever he detected gossip in the air. I never knew him talk about people unkindly: in fact, one almost knew that he did not care for a particular individual by his reticence. If he could not speak well of anyone, he said nothing.

More than anything else, birds, bees, flowers, everything, Ryle loved people. If they were unsuccessful, in misfortune, oppressed, sick, he loved them the more. His visits to India and South Africa, where he saw for himself the state of public health as affecting Indians and Africans, moved him terribly. Social conditions as affecting the physical well-being of the world were his abiding concern. That is why he felt such a strong compulsion to take up the Oxford chair. He believed that nations, populations, industries, groups, were as much pathological as individuals: that they are subject to special ills simply because they are organic. His thoughts were never long away from the problem that beset his intellect: how to find ways of highlighting these ills and, later, remedying them. The pathology of "Homo socius" was Ryle's consuming private and professional interest. It is an odd, but chastening, thought that his invariable kindness and charitableness was in fact the expression of his physician's outlook on the affairs of every day.

H. C.

Dr. Ryle was physician to H.M. Household from 1932 to 1936 and had since been physician extraordinary to the King. He was a member of the Medical Research Council from 1935 to 1939. He married in 1914 Miriam Power Scully and they had two daughters and three sons, one of whom is Dr. J. C. Ryle, medical officer of Shrewsbury School.

Prof. G. R. MINOT

George Richards Minot was a Bostonian in the proper sense. His ancestor, George Minot, of Saffron Walden, in Essex, emigrated to the new Bay State and was admitted a freeman of Dorchester, Mass., in 1634. A former George Richards Minot (1758–1802) was a distinguished jurist and one of the earliest historians of the colony. Minot was also descended from Dr. James Jackson, professor of medicine in Harvard University at the beginning of the 19th century.

He was known throughout the world as one of the discoverers of the liver treatment of pernicious anæmia, but it was perhaps as director of the Thorndike Memorial Laboratory that he made his greatest contribution to medicine. This experiment in using the brains and resources of a university medical school for the study of disease in a municipal hospital (the Boston City Hospital) was inspired by Francis Weld Peabody, a kinsman of Minot's, and one of Harvard's most brilliant medical teachers. When Peabody died at the age of 45, in 1927, Minot succeeded him as director of the "Thorndike."

This remarkable place occupies three unassuming floors in a small building in the huge City Hospital. There is a metabolic ward of about 20 beds and, above that, two floors of laboratories. It is not graced by polished benches, glittering furniture, or numerous assistants in sterile white coats, such as we often erroneously associate with American medical science. Under Minot's direction no funds were dissipated on non-essentials: everything went into equipment and staff. The equipment—crowded out from the rooms in each of which a number of workers amicably disputed a few inches of bench space—often overflowed into the corridors. Most British visitors felt instantly at home. But it was in choice of staff that Minot excelled. In 1937, in these cramped quarters, there were working Soma Weiss, William Castle (who excellently succeeds him as director), Chester Keefer, Maxwell Finland, Henry Jackson, Laskey Taylor, Hale Ham, Eugene Stead, Lowell Rantz, all of whom have contributed importantly to contemporary medical thought. There were others besides, and especially a steady turnover of about a dozen young men, of registrar status, from every part of the U.S.A., who came for one or two years to learn the scientific approach to medicine and return to preach the gospel in their native State. The Thorndike at this time played a leading part in the ferment of thought which has made Boston a famous medical centre in the great tradition of Padua, Leyden, Edinburgh, London, Dublin, Paris, Baltimore, Berlin, and Vienna.

Minot was a natural aristocrat, both by birth and feeling. The modern competitive struggle for success did not disturb him. In a land where hustle and snap-decisions often pass for efficiency, he was never in any hurry to come to the point. His conversation was discursive: thinking aloud would bring him slowly round to the point at issue, by which time the hustlers had often left: but those who waited for his final thought, learned wisdom. His tall, spare, lanky figure—a pile of books under his arm, and on his head a shapeless hat of the kind beloved by New Englanders—did not mark him out, among the present polyglot population of Boston, as one of that city's most distinguished citizens.

His industry was amazing. Besides directing the Thorndike Memorial Laboratory and the Harvard medical services in the Boston City Hospital, he was one of the full professors of medicine at Harvard and played a prominent part in the direction of its famous medical school. Yet he found time to read, and annotate with marginal notes, a great variety of medical journals. Often his staff would find on their desks on Monday morning a scribbled note on a scrap of paper drawing their attention to a recent article which they should have found for themselves, but had not. His own room in the Thorndike, with its library of journals and the fellowship diplomas of the British Royal Colleges hung on the walls, was constantly open to his staff, and in looking up a reference one was often rewarded by finding a marginal comment by G. R. M., expressing his views on its merits. He believed strongly that a medical scientist should be aware of developments in fields of science outside his own specialty and even outside medicine, and this was a discipline which he firmly imposed on himself. His advocacy of social medicine was disturbing to some of his contemporaries.

He was a master of detail. No letter ever went unanswered; a note from him, if not acknowledged in 24 hours, was usually followed by another, asking if it had been received. His secretary was once handed a notice to put up on the board. A pencilled spot, at the top of the paper, surrounded by a circle, was indicated by an arrow from a written directive: "Put thumb tack here." This was not his only eccentricity. A member of his staff, having made an appointment to see him, would often be greeted by the production of his watch. "Now let's see," he would say, "I can give you just 45 seconds—no, let's say, at a guess, 1 minute and 15 seconds." An hour later the young man would emerge, his head dizzy with the wide range of topics that had been brought to his attention.

Minot's keenest recreational interest was in plants. A British visitor, before the late war, remarked on the beauties of the American flowering dogwood that stands outside the hospitable Minot home in Brookline, and expressed surprise that the tree was so seldom seen in British gardens. Some months later, on returning to England, he was amazed to receive a consignment of three young dogwood trees.

In many ways Minot was detached from contemporary American life—a survival of the great cultural tradition of the 19th-century Harvard. It was in keeping with this 19th-century character that he maintained the almost dead art of correspondence with friends, and many in this country as elsewhere will feel with personal sorrow the passing of this remarkable man.

A. P. M.

BERNARD EDWARD GRANVILLE BAILEY

M.R.C.S.

Dr. Bernard Bailey, who died at his home in Midhurst on Feb. 4 at the age of 76, qualified in 1899 from St. Bartholomew's Hospital. He held house-appointments at the City of London Hospital for Diseases of the Chest, the East London Hospital for Children, and the Shoreditch Infirmary before he settled in practice at Midhurst in 1902. His partner writes: "Dr. Bailey loved the country and country people, and it was not only for his professional work and skill that he was loved there, but also for his willingness to help anyone, rich or poor, when they were in trouble. He was a keen supporter of the many activities of village life, and it is largely to his energy that we owe our cottage hospital."

Parliament

The King's Speech

THE opening sentences of the speech from the Throne, which the King delivered at the opening of Parliament on March 6, pointed out that the economic difficulties of the country have emphasised the need to expand the production of food from our own soil, and His Majesty's Government will continue to encourage the agricultural population to increase output by every efficient means and to make better use of marginal land. Legislation will be introduced to improve water-supplies, especially in rural areas. For the present session the Government propose only a limited programme of legislation, but it includes at least one Bill of importance to the medical profession. Amendments to the Medical Acts are to be introduced to raise the standard of medical education and to modify the constitution and disciplinary procedure of the General Medical Council. Legislation will also be proposed to vary the constitution of the Central Midwives Board and to make other alterations in the law relating to midwives.

Medical Peer

In the House of Lords on March 1, Lord Haden-Guest was introduced, took the oath, and subscribed the roll on his elevation to the peerage. His sponsors were Lord Webb-Johnson and Lord Shepherd.

Appointments

BACKUS, A. B., M.B. Lond., M.R.C.O.G.: senior registrar in gynæcology and obstetrics, Peterborough area.

CLARKE, P. J. H., M.B., B.SC. N.U.I., D.P.H., T.D.D.: asst. senior M.O., East Anglian Regional Hospital Board.

GRANGE, HELEN B., M.B. Lond.: asst. M.O., Essex county council, in dept. of area M.O. in borough of Ilford.

HASTILOW, IRENE M. D. F. C., M.B. Birm., D.OBST. R.C.O.G., D.C.H.: asst. county M.O. in the district of Bexley, Kent.

HODGSON, M. C., M.B. St. And.: appointed factory doctor, Aldershot district.

MCLEAY, CHRISTINA J., M.B. Edin.: medical adviser in mental health on the staff of the county M.O., Devon.

WATSON, W. A., M.R.C.S.: appointed factory doctor, Chatteris district.

Diary of the Week

MARCH 12 TO 18

Monday, 13th

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Prof. A. M. Boyd, Dr. Geoffrey Evans: Peripheral Arterial Disease.

Tuesday, 14th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. E. E. Pochin: Investigation of Thyroid Function and Disease by the Use of Radioactive Iodine. (First Oliver-Sharpey lecture.)
ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. M. R. Ewing: Villous Tumours of the Rectum. (Hunterian lecture.)
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. I. Muende: *Fungus Diseases of the Skin.*
CHELSEA CLINICAL SOCIETY
7.30 P.M. (South Kensington Hotel, 47, Queen's Gate Terrace, S.W.7.) Mr. R. C. Brock, Dr. Paul Wood: Modern Intrathoracic Surgery.
CHADWICK LECTURE
2.30 P.M. (Westminster Medical School, Horseferry Road, S.W.1.) Dr. C. A. Boucher: Maintenance of Health by the Prevention of Accidents in the Home.

Wednesday, 15th

INSTITUTE OF DERMATOLOGY
5 P.M. Dr. C. W. McKenney: X-ray Technique.
INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5
4.30 P.M. Dr. E. Stengel: Postgraduate lecture-demonstration.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Lieut.-Colonel E. F. W. Mackenzie: Provision and Maintenance of a Safe Water-supply for the Consumer.
UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Dr. J. D. Fraser: Glioma of the Retina.

Thursday, 16th

ROYAL COLLEGE OF [illegible]
5 P.M. Dr. Poch[illegible] Thyroid Function and Disease by [illegible] Iodine. (Last Oliver-Sharpey lecture.)
ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. E. M. Nanson: Respiratory Responses to Operative Trauma. (Hunterian lecture.)
UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, Gower Street, W.C.1
4.30 P.M. Prof. F. G. Young, F.R.S.: The Experimental Approach to the Problem of Diabetes Mellitus. (Sydney Ringer lecture.)
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE
7.30 P.M. (Royal Army Medical College, Millbank, S.W.1.) Laboratory [illegible]
NATIONAL HOSPITAL, [illegible]
5 P.M. Dr. J. Hagu[illegible] Forms of Disseminated Sclerosis.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION
8.30 P.M. (B.M.A. House, Tavistock Square, W.C.1.) Dr. Alice Stewart: Recent Work of the Institute of Social Medicine, Oxford, on the Epidemiology of Pulmonary Tuberculosis.

Friday, 17th

FACULTY OF RADIOLOGISTS
2.15 P.M. *Therapy Section* (Royal College of Surgeons). Mr. D. S. Poole-Wilson, Dr. J. M. W. Gibson, Dr. J. L. E. Millen: Carcinoma of the Bladder.
MAIDA VALE HOSPITAL MEDICAL SCHOOL, W.9
5 P.M. Dr. P. H. Sandifer: Neurological demonstration.
WEST LONDON MEDICO-CHIRURGICAL SOCIETY
7.30 P.M. (South Kensington Hotel.) Sir George Thompson, F.R.S.: Atomic Energy.

Saturday, 18th

MIDDLESEX COUNTY MEDICAL SOCIETY
3 P.M. (Shenley Hospital.) Dr. B. M. C. Gilsenan: Demonstration of cases. Dr. S. T. Hayward, Miss Darby (*psychiatric social worker*), Miss E. Macdonald (*psychologist*): Three Aspects of One Voluntary Admission.

Notes and News

GUY'S HOSPITAL DENTAL SCHOOL

THE annual clinical meeting of Guy's Hospital dental school was held on Saturday, March 4. This event, the largest of its kind in the Commonwealth, was attended by about 500 Guy's men, to whom it provided an opportunity of seeing new developments in dentistry, and of renewing old friendships. In the comparatively short time since the last clinical meeting, great changes have been made in the dental school; the foot-engine has become a thing of the past and the students work with equipment equal to the best in private practice. An extension to the conservation room is to be opened in May, and the old pathology block is being re-equipped for the use of students in the preclinical period. At present, some 70–80 students qualify each year from the hospital.

The outstanding feature of this year's meeting was the demonstration of colour television, arranged by Messrs. Pye, of Cambridge. This was the first occasion on which colour television of surgical operations had been demonstrated in public. The principle underlying colour television is simple; but at the moment technical considerations, such as the great band-width required, preclude its use except over a closed circuit. The number of lines—405—is the same as that of the B.B.C. system, but the frame-frequency of 75 per sec. is three times as great. A disc, with red, blue, and yellow sectors, rotates in front of the camera, and is synchronised with a similar disc in front of the screen so that one frame of each colour is seen in $^1/_{25}$ sec., thus building up a fully coloured image. The colour rendering is good, but the major problem to be overcome is that of providing adequate illumination at the back of the mouth or in a deep wound cavity. The use of colour photography for both record and teaching purposes has increased in the past year, and a special deep-focus camera for oral photography has been developed by Mr. J. M. Dyce, director of the photographic department. Mr. D. J. Anderson, of the dental research laboratory, demonstrated the use of the strain-gauge—already well known in heavy engineering—for determining the biting pressures exerted by natural teeth. In the department of preventive dentistry the experiments to determine the efficacy of a 2% solution of sodium fluoride in the control of caries are being continued; and further experiments are being carried out with vitamin K in chewing-gum.

PROTECTION AGAINST MIDGES

A NEW formula for a protective midge cream has been worked out by the subcommittee on midge control of the Scottish Scientific Advisory Committee. This formula, said to be an advance on that devised in 1946,[1] is the outcome of investigation at the Royal Technical College, Glasgow, by Prof. J. P. Todd and Mr. A. B. Gilmour. The formula is: dimethyl phthalate 200 g., magnesium stearate 30 g., zinc stearate 70 g. In preparation dimethyl phthalate is first levigated with magnesium stearate, then zinc stearate is gradually incorporated. Like the 1946 preparation, this cream does not harm the skin, although there may be some slight tingling when it is first applied and afterwards when washing the face. It should not be allowed, however, to get into the eyes, nor should it come into contact with tortoise-shell or plastic spectacle frames. This new cream is alleged to ward off midges for at least three hours; and it is not washed off by perspiration.

CONTRIBUTORY SCHEMES

IT is more than eighty years since workpeople first systematically collected contributions in support of voluntary hospitals. The difficulties which the hospitals experienced during the 1914–18 war led to a wider organisation of this form of support. The corporate spirit of provincial cities was enlisted in these schemes, but nobody expected that the movement could have the remarkable success which was attained in London by the Hospital Saving Association. The provincial contributory schemes, largely owing to the need for reciprocity in their benefits, combined in 1930 in the formation of the British Hospitals Contributory Schemes Association. Mr. A. T. Page has provided a record of its establishment with an account of the proceedings at conferences and a copy of the new constitution rendered necessary by the passing of the National Health Service Act. The book (*Pennies for Health*, published by the Association[1]) provides a useful though somewhat biased chapter in the history of a remarkable movement in the social life of this country; the end of which is not yet. There are signs that public opinion, growing in the reorganised bodies, will press for more attention to health and the measures to promote it.

HARVEY IN HIS PORTRAITS

William Harvey's images are the happy study of Mr. Geoffrey Keynes. His Thomas Vicary lecture of 1948 has already been published by the Royal College of Surgeons,[2] and now the Cambridge University Press[3] have given us his Linacre lecture—*The Personality of William Harvey*—delivered at St. John's College, Cambridge, in May, 1949. Here there are fewer pictures but more text; and the character of the penetrating irascible active little doctor comes lively from the page. A few months before giving the lecture Mr. Keynes had the felicity of identifying a long-ignored portrait of Harvey, one of a set of family portraits, in a derelict house—Rolls Park, near Chigwell in Essex. These portraits are now safely housed in the National Portrait Gallery—a treasure trove we all can share.

University of Manchester

Dr. H. G. B. Slack has been appointed senior research assistant in the chronic rheumatism centre.

University of Glasgow

On Feb. 25 the degree of M.D. was conferred in absentia on Oliver Gray.

University of St. Andrews

On April 20 the honorary degree of doctor of law will be conferred on Mr. A. E. Porritt, a surgeon to the King and surgeon to St. Mary's Hospital, London, and on Mr. H. B. Stallard, ophthalmic surgeon to St. Bartholomew's Hospital.

International Congress of Radiology

The 6th International Congress of Radiology will be held in London under the presidency of Dr. Ralston Paterson in the week beginning July 24. A scientific exhibition and a technical exhibition will be held in connection with the congress.

British Medical Students Association

On Tuesday, March 14, at 5.30 P.M., at the London Hospita E.1, Dr. Alice Stewart will speak on Social Medicine.

University Grants Committee

Prof. G. W. Pickering, who lately completed his original term of office on this committee, has consented to serve for a further five years from Nov. 1, 1949.

Royal Medical Foundation of Epsom College

Applications are invited for the following scholarships and pensions:

St. Anne's scholarships for girls attending Church of England schools. Candidates must be fully 9 years of age and the orphan daughters of doctors who have been in practice in England or Wales for not less than 5 years.

Pensions for necessitous medical men fully 55 years of age, and for the widows and spinster daughters of doctors.

Scholarships and grants for boys or girls, not necessarily orphans, who are of public-school age.

Further information may be had from the secretary, Epsom College, Surrey.

World Health Organisation

Major-General Sir Sahib Singh Sokhey, director of the Haffkine Institute, Bombay, has been appointed assistant director-general of W.H.O.

Major-General Sokhey, who was born in 1887, qualified at the University of Edinburgh in 1911. Two years later he joined the Indian Medical Service, and in the first world war he served in Europe, Mesopotamia, and Egypt. He has been associated with the Haffkine Institute since 1925, and was appointed to the directorship in 1931. He was knighted in 1946.

Dr. G. Brock Chisholm, the director-general, left Geneva on March 2 for a five weeks' visit to the U.S.A., New Zealand, and Australia.

2. See *Lancet*, 1949, ii, 922.
3. Pp. 48. 5*s*.

British Health Resorts Association

A meeting of this society will be held today, Friday, March 10, at 4 P.M., at 11, Chandos Street, London, W.1.

Congress of the International Academy of Forensic and Social Medicine

This congress, which was to have been held this month in Cairo, has been postponed for the time being.

Conference on Amœbiasis

The spa of Châtel-Guyon in Auvergne is holding an international congress on Sept. 15 and 16 on amœbiasis and other intestinal parasitoses in the adult and child. Further information may be had from the general secretary, Grands Thermes, Châtel-Guyon (Puy-de-Dôme).

Birmingham and Midland Obstetric and Gynæcological Society

Dr. A. T. Hertig, professor of pathology at Harvard University, will speak on Wednesday, March 29, at 4.30 P.M., in the Medical School, Birmingham, on the Genesis of Cervical and Endometrial Carcinoma with respect to the In-situ Stage.

European Congress on Allergy

The first European Congress on Allergy will be held on May 31 and June 1 at the Hôpital Broussais, 96, rue Didot Paris XV, under the presidency of Prof. Pasteur Vallery-Radot. Sir Henry Dale, O.M., is honorary president. Further particulars may be had from the secretary-general, Dr. Blamoutier, 5, rue de Luynes, Paris, VII.

Biological Assays

The Biometric Society (British Region) and the biological methods group of the Society of Public Analysts and Other Analytical Chemists at 2.45 P.M. on Tuesday, March 14, at 11, Chandos Street, London, W.1, will hold a symposium on the Design and Evaluation of Biological Assays. Dr. J. W. Trevan, F.R.S., will be in the chair.

Research into Leukæmia

The Robert Roesler de Villiers Foundation, of 417, Park Avenue, New York, 22, are offering a prize of $500 (or in special circumstances $1000) for the most significant contribution to the knowledge of the nature, causes, origin, treatment and cure of acute leukæmia and allied conditions.

The work must be published, or accepted for publication, by a reputable journal in or outside of the United States of America, between Jan. 1, 1950, and Oct. 20, 1951. In exceptional circumstances the publication requirements may be waived. The prize has been instituted in memory of Robert Roesler de Villiers, who died of acute leukæmia at the age of 16 in 1944. Further particulars may be had from the foundation, from Dr. Sven Moeschlin, Kantonsspital, Zurich, or from Dr. S. Haberman, 3301, Junius Street, Dallas, Texas.

Peckham Health Centre Closes

On March 4 the Pioneer Health Centre at Peckham closed. Founded in 1926 by Dr. Scott Williamson and Dr. Innes Pearse, it has been supported by voluntary contributions. Each year it cost £25,000 to maintain and last July there was a deficit of £12,000. The centre was really a family club where parents and children could each find the recreation that suited their age and taste. Members were only accepted on a family basis and each family paid 2*s.* a week. Each of its members had an annual medical examination. Suggestions have been submitted to the London County Council that it might be used as a National Health Service experimental centre, research institute, and family club.

Doctors' Lists

At the end of 1948 the Ministry of Health proposed that doctors with an excess list should be asked not to accept additional patients (see *Lancet*, 1948, ii, 913). Executive councils have now been advised by the Ministry to " consider availing themselves where necessary of the powers of the Allocation Scheme to require practitioners within a reasonable time to take appropriate action so as to bring their lists within the prescribed limits." It is suggested that, to allow for inflation in executive-council registers and to give some margin against possible withdrawals, councils should allow a tolerance of, say, 5% above the permitted limits. Some executive councils have already taken advantage of the provisions of the allocation scheme, but " the number of practitioners with lists in excess of the prescribed limits remains substantial."

Joint Tuberculosis Council

Dr. Norman England has lately resigned the honorary secretaryship of the council. Dr. R. L. Midgley succeeds him in this office. Dr. Midgley's address is Hawkmoor Sanatorium, Bovey Tracey, S. Devon.

Photography and Cinematography by Invisible Radiation

The scientific and technical group of the Royal Photographic Society and the sciences committee of the Scientific Film Association are holding a discussion on this subject on Saturday, April 15, at the London University Institute of Education. Further information may be had from the association, 4, Great Russell Street, London, W.C.1.

Dr. C. H. Andrewes, F.R.S., director of the Medical Research Council unit working on the common cold at Salisbury, is visiting Italy to give some lectures for the British Council.

Copies of *Spas in Italy*, a short descriptive booklet of the Italian thermal stations, may be had post free from the Italian State Tourist Department, Kendal House, 1, Conduit Street, London, W.1.

The proceedings of the first post-war congress of the International Hospital Federation, held last summer in Holland (see *Lancet*, 1949, i, 1063), have now been published. The book may be obtained (non-members £1 1*s.*, members 10*s.* 6*d.*) from the federation, c/o King Edward's Hospital Fund for London, 10, Old Jewry, London, E.C.2.

Careers Guide: Opportunities in the Professions and in Business Management is the title of a handbook issued by the appointments department of the Ministry of Labour and National Service in conjunction with the Central Youth Employment Executive (H.M. Stationery Office. Pp. 132. 2*s.* 6*d.*).

The *South African Journal of Clinical Science*, which is at first to be published quarterly, will supplant *Clinical Proceedings*. The new journal, of which the first issue appears this month, is sponsored by the South African Medical Association, the Cape Town Post-Graduate Medical Association, and the South African Institute for Medical Research. Subscriptions (25*s.* per annum) should be forwarded to P.O. Box 643, Cape Town.

CORRIGENDUM: *The Systemic Collagenoses.*—In the 11th line from the end of this annotation last week (p. 409) the word " hypoergy " was given wrongly as " hyperergy."

Births, Marriages, and Deaths

BIRTHS

BLACK.—On Feb. 28, the wife of Dr. D. A. K. Black—a son.

CAYLEY.—On Feb. 26, in London, the wife of Dr. F. E. Cayley, M.B.E.—a son.

CUTHBERT.—On Feb. 27, at Ruislip, the wife of Dr. O. D. Cuthbert—a daughter.

DIXON.—On Feb. 25, at Cheltenham, the wife of Dr. D. G. Dixon—a son.

ROGERS.—On Feb. 25, at Newick, Sussex, the wife of Dr. Anthony Rogers, of Hamilton, New Zealand—a daughter.

SIMPSON.—On March 2, in London, the wife of Mr. John F. Simpson, F.R.C.S.—a daughter.

STORMONT.—On Feb. 28, at Ilfracombe, the wife of Dr. A. Stormont—a daughter.

WADDY.—On March 2, at Winchester, the wife of Dr. Broughton Waddy, Medical Service, Gold Coast—a daughter.

WILSON.—On Feb. 25, at Ludham, Norfolk, the wife of Dr. P. R. Wilson—a daughter.

WYMAN.—On Feb. 26, in London, the wife of Dr. J. B. Wyman—a son.

MARRIAGES

CAMPBELL—KENNEDY.—On Feb. 25, at Aldershot, Ronald Wilson Campbell, captain, R.A.M.C., to Margaret Mary Kennedy, M.B. St. And.

KAY—BARKER.—On Feb. 25, at Selsdon, Surrey, Mark S. Kay, B.M., to Ann Barker.

DEATHS

BECKETT-OVERY.—On Feb. 27, in London, Harry Beckett-Overy, M.D. Edin., F.R.C.S.

DUIGAN.—On March 2, Victor John Duigan, M.R.C.S., of Gorleston, aged 73.

GIBBS.—On Feb. 26, at Woking, Andrew Armstrong Gibbs, L.R.C.S.I., major-general, I.M.S.

GIBSON.—On March 2, at Petersfield, Percy Lemprière Gibson, D.M. Oxfd, surgeon captain, R.N. retd.

HODGE.—On March 2, at Glasgow, Ronald Dingwall Hodge, M.B. Glasg.

RYLE.—On Feb. 27, John Alfred Ryle, M.D. Lond., F.R.C.P., aged 60.

UNDULANT FEVER

A NEGLECTED PROBLEM*

Sir WELDON DALRYMPLE-CHAMPNEYS
Bt., M.A., D.M. Oxfd, F.R.C.P., D.P.H.
DEPUTY CHIEF MEDICAL OFFICER, MINISTRY OF HEALTH

(Concluded from p. 435)

CLINICAL TYPES

Many patients, as I have said, go to their doctor with a history of increasing tiredness, perhaps with headache, and are found to have a temperature of 102–104°F. However, the commonest symptom, sweating, usually occurs early in the disease, and by its persistence, diurnal regularity of onset, intensity, and sometimes characteristic odour constitutes a valuable diagnostic indication. The onset may on the other hand be extremely sudden and even alarming, especially when accompanied by hæmorrhages from the lungs or bowel, under the skin, or in the joints, or by severe thoracic or abdominal pain simulating pleurisy or peritonitis.

Many different authors have tried to classify their cases on the basis of general severity, character of the temperature chart, preponderance of certain symptoms, duration, &c. When dealing with so variable a disease, no classification can be entirely satisfactory, and I have therefore adopted, in table VIII, a mixed classification which gives a general idea of the commonest variations encountered in my series, whilst side by side—but not always corresponding to their opposite numbers—I have placed the commonest types of temperature charts.

TABLE VIII—CLINICAL CLASSIFICATION

Types of case	Types of fever
Ambulant	
Undulant	Undulant
Moderate continuous or daily remittent	Daily remittent
Moderate relapsing	Irregular or indeterminate
Nervous and toxic	
Malignant and hæmorrhagic	

Ambulant

When first seen by their doctors many patients are either still ambulant or give a history of increasing weariness, headache, and sometimes anorexia some weeks previously. But there are also cases in which the patient remains ambulant throughout, or nearly throughout, his illness. These must often be missed altogether, because of the mildness of the disease or its short duration or both, and many workers in America believe that such patients often pass into the condition known there as "chronic brucellosis," their symptoms being attributed to neurosis, rheumatism, septic foci, and the like. Of the 68 cases in my series lasting a fortnight or less some were of this type. These patients often suffer from headache, feelings of chilliness, fatigue, impairment of appetite, perhaps mild nasal or bronchial catarrh, and little else.

Undulant

This is the commonest type in this country, but not, apparently, in the United States, since Huddleson,[52] writing of the temperature curve regarded by Hughes [53] as typical of brucellosis in the Mediterranean region, states that he and his associates as yet "have not encountered a single chart which conformed closely to the type so frequently described." Unless the word "closely" excludes any chart in which variations of type occur at some period of the illness, my experience here has been very different to his. Of the 280 temperature charts available in my cases, 149 (53·2%) showed typical undulations at some time, and in most of them such undulations were an outstanding feature. A typical chart of this kind is shown in fig. 11.

Corresponding to these undulations there is daily exacerbation of symptoms such as headache, fatigue, malaise, anorexia (often only during the period of the day when the fever is at its height), sweating, aching of the limbs and back, and perhaps arthralgia and sore throat. These daily exacerbations become more and more pronounced as the undulation reaches its peak, fading away gradually as the line of the daily crests declines toward normal. In some cases, or during some phases of a particular case, these waves are continuous for an extended period without a return of the temperature to normal; at other times an apyrexial period of a few days separates the waves. Often towards the end of the illness these intermissions become longer, but one often sees either a sudden and unexpected cessation of the fever when apparently in full swing, or one or two isolated waves following an apyrexial interval of such length as to give good hope that the illness is at an end. Sometimes, as other workers have pointed out, there seems to be an overlapping of waves which gives an irregular appearance to one or more sections of an otherwise typical undulant chart.

Moderate Continuous or Daily Remittent

This is a much smaller group of cases, in some of which the fever never rises above 99°F, either remaining just above normal for long periods or returning daily to normal or below, whilst in other cases the temperature fluctuates more but returns daily to the normal line or near it (fig. 12). Apart from the symptoms already described in connection with the ambulant type, such patients suffer from sweating, constipation, pains in the limbs, joints, or back, or perhaps an occasional mild rigor. In my series of 280 patients for whom a temperature chart was available 31 (11·1%) showed this type of fever.

Moderate Relapsing

Many patients, however, show a more irregular type of fever, with afebrile intervals of several days or even several weeks followed by a moderate exacerbation for a limited period, and these alternations may continue as long as several months. Such cases constitute a rather indefinite proportion of the 100 patients (35·7% of the 280 temperature charts) grouped under the heading of "irregular or indeterminate" (fig. 13). During their pyrexial periods these patients suffer from much the same symptoms as do those in the last category, but even when free from fever they are seldom entirely free from symptoms—a useful point in prognosis, as I shall show. Often, moreover, enlargement of the spleen, and also perhaps of the liver, is found, and arthritis or arthralgia is fairly common.

Nervous and Toxic

The nervous manifestations which may occur in this disease I shall mention presently. There is a type of case, usually of sudden onset, in which such manifestations are particularly conspicuous, and seem to be attributable to toxic causes rather than to definite invasion of the nervous system by the causative organism. As a rule such patients are not very seriously ill and often their fever is moderate throughout, though they may have extreme depression and even suicidal tendencies. On the other hand the presence of circulating toxins in large amounts can be serious for elderly or debilitated patients.

Malignant and Hæmorrhagic

The malignant type is rarer in this country than in the Mediterranean as described by Hughes.[53] It is usually an extreme instance of the toxic type just described, and is marked by severe headache, anorexia, thirst, nausea, and even vomiting. Mental disturbances are common and at the end there is often delirium followed by coma.

---

* The Milroy lectures for 1950, delivered before the Royal College of Physicians on Feb. 14 and 16.

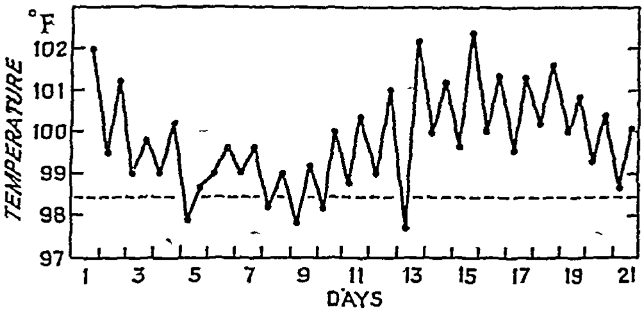

Fig. 11—Undulant type of fever.

The face is usually flushed, the tongue thickly coated, especially in the middle, the breath offensive, the spleen and perhaps the liver enlarged. Bronchial and even pneumonic involvement are common, and hæmorrhage from the bowel and perhaps elsewhere sometimes occurs and usually heralds a fatal outcome (as in 4 of my 19 fatal cases).

SIGNS AND SYMPTOMS

There is, perhaps, no more difficult disease to diagnose clinically than undulant fever: its manifestations are protean (230 different signs and symptoms were reported in my cases) and its mildness and short duration often lead the physician to content himself with a diagnosis of "feverish cold," "influenza," or merely "pyrexia of uncertain origin (P.U.O.)." At the same time knowledge of the commonest signs and symptoms will often arouse a suspicion, the truth of which can usually be tested by laboratory methods, and it is very important to bear in mind the possibility of this diagnosis when certain of the less common signs and symptoms occur, so as to save the patient from unnecessary therapy including major surgical interference. The twelve commonest signs and symptoms in my series, with the numbers of cases in which they were recorded, are shown in table IX.

TABLE IX—TWELVE COMMONEST SYMPTOMS IN ORDER OF FREQUENCY

Sweating	757	Constipation	409
Weakness	694	Rigors	328
Headache	626	Spleen enlarged	213
Malaise	600	Cough	184
Anorexia	534	Sore throat	156
*Pain	524	Arthritis or arthralgia	109

* Other than headache, arthralgia, or abdominal pain.

Sweating is sometimes moderate or slight, but more usually drenching. It occurs with the fall of temperature in the afternoon or evening, and sometimes (though not nearly so often in *Br. abortus* infection as in the *Br. melitensis* infection of "Malta fever") it has a characteristic sour odour.

Weakness and fatigue may be troublesome even when the fever is slight and other symptoms inconspicuous; but on the other hand the patient often recovers strength with a rapidity quite at variance with the height of the fever from which he has been suffering.

Headache is usually either frontal or occipital, but it is also commonly described by the patient as "burning," "burning behind the eyes," or "eyes full of hot sand." Headache of any type is often very intense and may be long continued. It had led to a diagnosis of meningococcal meningitis in 3 of my cases and of tuberculous meningitis in 1.

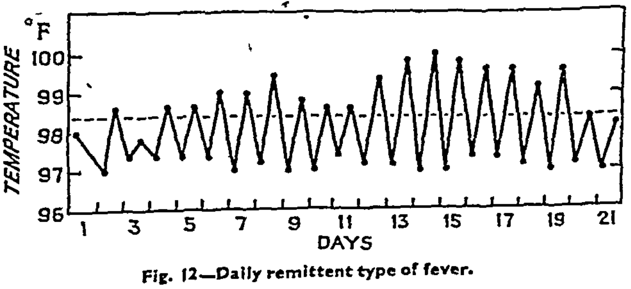

Fig. 12—Daily remittent type of fever.

Pain, apart from headache, abdominal pain, or arthralgia, is usually located in the muscles of the limbs or of the back (chiefly the lumbar region). Abdominal pain however occurred in 79 of my cases and is important because it may lead to serious mistakes in diagnosis. Thus pain in the right iliac fossa was attributed to appendicitis in 2 of my cases, and pain in other parts of the abdomen to cholecystitis (4 cases), † nephritis or perinephric abscess (2), gastritis (4), and tuberculous peritonitis, pyelitis, and hepatitis (1 each).

Digestive disturbances are common. The commonest (as the table IX shows) is *anorexia,* but nausea was noted in 34 cases and vomiting in 56. Though *constipation* was recorded in 409 cases, there was diarrhœa in 56 of my cases, and sometimes these conditions alternate.

When there are *rigors* (fig. 14) they are usually infrequent or at any rate confined to a short phase of the illness. A cold feeling which may or may not go on to a shivering attack is very common and was well described by one of my patients as "an intense cold which is not just chilliness but amounts to an actual pain and sometimes will not give way even in a hot bath." Pains in the joints are frequent, but true arthritis is far less common in *Br. abortus* than in *Br. melitensis* infections.

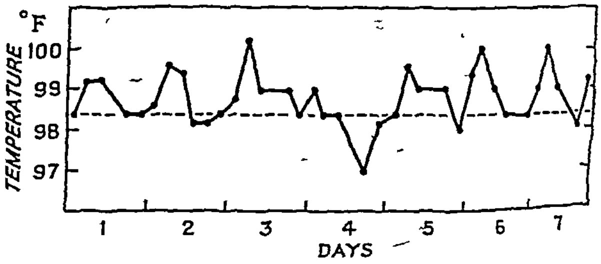

Fig. 13—Irregular type of fever.

Organisms of the brucella group often cause enlargement (and sometimes tenderness) of the *spleen,* which in this country seldom extends more than one to three finger-breadths below the costal margin. The evidence suggests strongly that when the disease becomes chronic it is here that the causative organism often lurks. Enlargement of the *liver,* though not so common (48 of my cases), is a valuable sign; but it is remarkable that in only 3 cases was the liver tender as well as swollen.

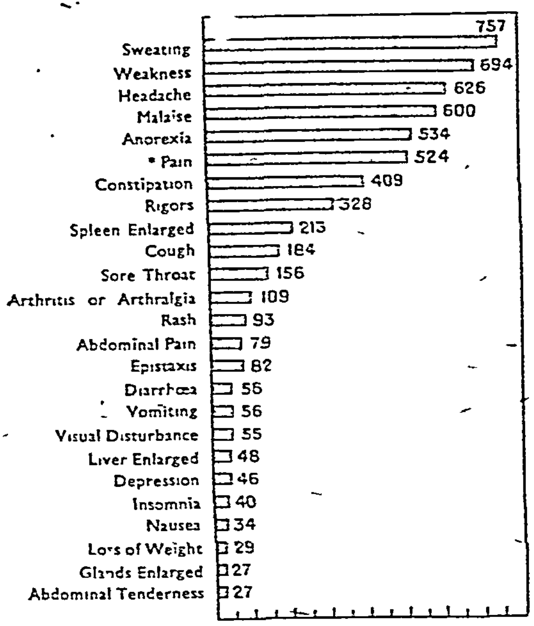
The *respiratory system* is often invaded; though there may be no more than a slight nasal or bronchial catarrh or a sore throat, yet frank bronchitis, pleurisy, or pneumonia are occasionally encountered.

Any long-continued fever is apt to affect the patient's *nervous system,* and this must be especially true of one which fluctuates up and down day after day and week after week for months, or is continually encouraging false hopes of cure by intermissions of several days followed by the same familiar and hated burning afternoons and drenching nights. It is not, therefore, surprising that, besides mere depression and apathy, one sometimes sees such features as anxiety, amnesia, aphasia, aphonia, childishness, deafness, delusions, hallucinations, dizziness, drowsiness, delirium, various phobias, irritability, somnolence, and suicidal tendencies. Some of these symptoms are probably due to pathological changes in the central nervous system (fig. 15).

The *blood system* is seldom severely affected, but hæmorrhages do sometimes occur from the nose, throat, ears, lungs, or bowel—particularly the nose. In 1

---

† The gall-bladder is a favourite lurking-place of brucella, which therefore is presumably a cause of cholecystitis. Tenderness of this organ was noted in 24 of my cases.



* Other than headache, arthralgia, or abdominal pain

Fig. 14—Frequency of the commonest symptoms in 983 cases of undulant fever.

of my cases a retinal thrombosis caused permanent blindness in one eye. Brucella occasionally invades the *heart* causing endocarditis, described in England by Rennie and Young [77] and in other countries by Hardy et al.,[44] Olin,[71] Spink et al.,[89] and Uhlhorn.[91] My series contains 1 case of myocarditis and 1 of pericarditis. Changes in the heart's rhythm are seldom pronounced or characteristic: bradycardia is commoner than tachycardia.

Rashes of various kinds occurred 93 times in my series, but none is pathognomonic. The commonest forms of rash were roseolar, as in typhoid fever (16%),‡ papular (13%), urticarial (9%), and erythematous (8%).

As already stated, *arthritis or arthralgia* is a fairly common feature of the disease in this country, affecting 109 of my cases. But whereas in the Mediterranean form of the disease effusion often develops (Hughes [53] noticed it in some 40% of his cases), in my series it was usually limited to transient pain, often flitting from joint to joint. Occasionally, however, a true effusion has occurred, with or without pain, and 1 patient had an acute, painful spondylitis similar to those described by some American workers.[9] [44]

Though *abortion* is the outstanding clinical feature of brucella infection in cattle, goats, and sheep, it is uncommon in pregnant women (Buser-Plüss,[16] Janbon and Caderas de Kerleau,[55] Zeller[100]). Nevertheless, among the 189 females in my series between fifteen and forty-five years of age there were 5 abortions. Of 2 patients who became infected during their pregnancy neither aborted, though in 1 of them the fever persisted for about eight months after her delivery at full term.

DURATION AND TERMINATION

My experience, in agreement with that of workers in other countries, has been that, in the absence of any specific treatment, the disease may terminate in a few days or may last for many years, and that its mode of termination may be sudden or gradual. Some patients show extraordinary resilience in the face of long-continued illness—such fortitude being perhaps commoner in abortus than in melitensis infections where rheumatic manifestations are more usual in the later phases.

The first patient seen by me in this country had apparently contracted the disease at Sydenham in 1886; for her symptoms had been exactly the same from that time until she came to me in 1929—except for a three-year period of freedom from 1918 to 1921, which of course raises the possibility of a reinfection. In 1932 she became afebrile and she was still so when I saw her last in 1936, though unfortunately in 1933 she had developed diabetes.

During all this long period she had felt fairly well in the morning, but about the middle of the afternoon the temperature would rise, with burning headache and the feeling that her eyes were full of hot sand, a sensation of violent heat or intense cold amounting at times to actual pain, and finally drenching perspiration lasting for a considerable time and soaking through her clothes, necessitating sometimes several changes of underclothes or night-clothes within an hour or two. During these attacks ocular accommodation was disturbed, making it impossible for her to read and eventually forcing her to give up needlework. In addition she suffered from pains in the back, lassitude, depression, insomnia (sometimes severe), constipation, and frequent nasal and bronchial catarrh. She told me that the disease had spoilt her life, for she could never accept a late afternoon or evening invitation owing to these drenching sweats, which were of the sour-smelling variety. Yet in spite of this long martyrdom she appeared, at the age of 60 when I first saw her, little different from a healthy woman of her age, except for some pallor and an unusually quiet demeanour.

This lady was, for many years, regarded by her family and her doctor as suffering from "nerves," and her temperature was not even taken until she contracted malaria in Ceylon in 1928—i.e., after 42 years of undulant fever. Another lady in my series, who had suffered from the disease for between eleven and thirteen years, was condemned by the same diagnosis of "nerves" to this long period of mental as well as physical suffering.

Even in cases of more normal duration, the frequency of intermissions and the usual failure of treatment to bring more than a slight alleviation make this a particularly trying disease. A good description of a case of moderate severity given to me by the physician was "a long, wearisome and most crippling form of illness, for the patient was not ill enough to compel him to stay in bed and yet was not well enough to go about his work."

DIAGNOSTIC CRITERIA

Workers in this field differ widely in their opinion on the criteria for diagnosis. Too lenient a standard will not only distort our knowledge of the disease but may

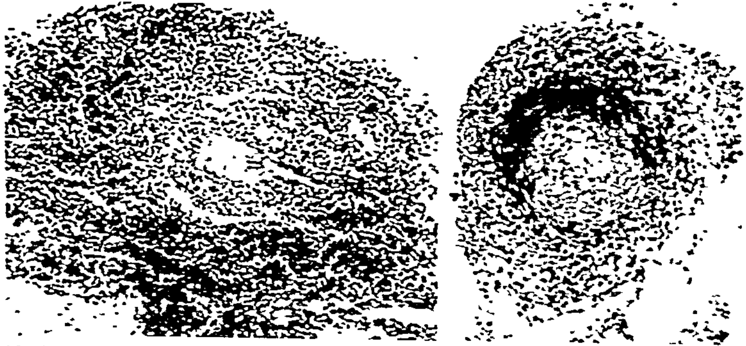


Fig. 15—Sections of human brain (×130) showing lesions due to brucella. Left: dense collar of lymphocytes around a meningeal vessel. Right: infiltration of lymphocytes around a brain-stem artery, showing much destruction of the media, with connective-tissue replacement. (After Hansmann and Schenken, *Amer. J. Path.* 1932, 8, 435.)

---

‡ It is interesting to note that Hughes [53] remarks that this rash "is seldom well developed in enteric fever cases in Malta, though present in some 70% of English cases."

also result in failure to treat the patient for some other condition from which he is really suffering. On the other hand too strict requirements will entail the missing of cases of undulant fever and deprive the patient of the benefit of treatment which is at long last showing some promise of effectiveness: they may condemn him to ineffective, distressing, and perhaps dangerous treatment for some other complaint from which he is not suffering; and the result may well be a serious attack on his mental integrity.

The criteria which I adopted for my series were:

1. Positive culture from the blood or other tissues.
2. A clinical picture consistent with undulant fever.
3. Agglutination by a standard brucella antigen to a titre of not less than 1 in 100.§

Positive culture, combined with a satisfactory clinical picture, is perhaps the only wholly satisfactory criterion; but in its absence a good clinical picture plus positive agglutination has seemed to me sufficient for practical purposes. The value of these and other criteria must now be briefly discussed.

Culture

By using a suitable technique (involving such precautions as suitable media, the use of an atmosphere containing an increased proportion of carbon dioxide, frequent subculturing and the continuation of culturing for at least twenty-eight days) it is often possible to isolate brucella from the blood, and less often from the spleen, urine, fæces, tonsillar swabs, bile, lymph-glands, sternal marrow, and abscesses (including osteomyelitis), and from the vagina and placental surface in cases of abortion. Unfortunately in this country culture is attempted far too seldom (only 239 times in my series) and too half-heartedly; and the statement of McCullough [63] in the United States is worth noting—that blood-culture should be attempted daily for a minimum of seven to ten days in any case in which undulant fever is strongly suspected, and that in his experience "we have yet to see a patient in the first six months of illness, in whom we seriously suspected brucellosis, from whom the organism was not recovered."

Though blood-culture is more likely to be successful when the temperature is high, it may succeed in the late stages of the illness when the temperature is normal, or even some time after apparent recovery (Olin [71]). It is sometimes positive in the continued absence of demonstrable blood agglutinins, and the organism may even be isolated when no actual fever has been detected, as occurred in one of my cases.‖

Agglutination

Strictly speaking, the agglutination test is a satisfactory criterion only if the antigen used is itself satisfactory; and unfortunately neither our own "standard" antigen nor the great variety of those employed in other countries can be regarded with complete equanimity. We have, however, two great advantages in this respect over our American colleagues—namely, that, speaking generally, we employ only a single antigen instead of a great variety, and that the chief disease in which cross-agglutination occurs, tularæmia, is unknown in this country. The value of this test is, however, greatly enhanced if it be repeated periodically; for a rising titre, when found, confirms the presence of active brucella infection (just as it does in the case of the enteric group).

Fortunately in most cases a fairly high reading is given, as will be seen from fig. 16. A negative result on the other hand, is of little value; for even when agglutinins eventually develop they take at least five days, and often much longer, to do so (in my series, it was thirty-five days in one case and a year in another, before they appeared); and, as I have shown, they may never appear at all in a long illness, even when the organism is grown from the blood.

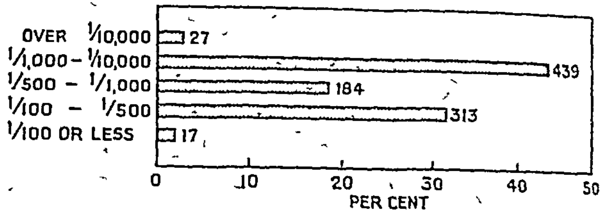

Fig. 16—Agglutination titres in 980 cases of undulant fever.

I have already mentioned the frequency of "prozones" in agglutination tests with brucella, and the importance therefore of employing a wide range of serum dilutions in the performance of this test, at any rate when the use of a more limited range has given a negative result.

Complement-fixation Reaction

This reaction is more widely employed in the United States than here. Its chief use is as an additional test when agglutination is negative, the two reactions being apparently quite unrelated. It does not, however, give a positive result as early in the disease as the agglutination test.

Intradermal Test

This test is used to detect specific sensitivity to brucella antigens, the antigen employed in this country ¶ being a preparation named "brucellin," an extract prepared from organisms of the brucella group, according to Olin's technique, by the Public Health Laboratory Service. The test is carried out by the injection of 0·1 ml. of brucellin into the skin of the forearm. A positive reaction is characterised by the appearance, in four to forty-eight hours, of a slightly raised, sometimes tender, œdematous plaque, 2–6 cm. in diameter, distinguished by its redness from the surrounding skin. A simple erythema, unattended by œdema, induration, or tenderness, which disappears in twenty-four hours, may be regarded as negative.

A negative reaction is strong evidence of the absence of recent brucella infection, but a positive reaction merely indicates that the patient has been sensitised by either past or present experience of brucella. The chief value of the test is therefore for retrospective diagnosis or to exclude undulant fever in cases in which blood-culture and the agglutination test have given negative results, though the patient is suffering from a febrile illness resembling undulant fever; but according to Foshay [33] it is occasionally negative where there is a positive blood-culture. It was employed in only 16 of my cases, in all of which it was positive, though very feebly in 3. In another 3 cases in which it was strongly positive though the agglutination titre was low (1 in 50, 1 in 100, and 1 in 125) it helped to confirm the diagnosis. In my opinion it could with advantage be employed more often in doubtful cases.

Opsonocytophagic Test

This test has been freely employed by Huddleson and other American workers, who claim that in combination with the agglutination reaction and the intradermal test it shows whether a patient is actively infected with brucella, has acquired immunity from past infection, or has had no experience of this organism. For instance

---

§ I have made 5 exceptions to this rule. In 3 cases blood-culture was positive, though agglutination was consistently negative, and in the other 2 cases the agglutination titre was 1 in 50 or 1 in 80 but the clinical picture and/or the intradermal test seemed to justify the diagnosis.

‖ Such findings seem to me the best argument in favour of the American use of the name "brucellosis" in place of the historical equivalent "undulant fever" bestowed on it by Hughes.

¶ In the United States Huddleson's "brucellergen," a preparation of the nucleoprotein fraction of brucella, is very generally employed for this test.

Huddleson[52] suggests that with a positive intradermal test and an opsonocytophagic power of 0–40% of cells (using his technique) the patient should be regarded as infected whether the agglutination test is positive or not. On the other hand, when the opsonocytophagic power is 60–100% and the intradermal test is positive, the patient should be regarded as "immune," whatever the answer given by the agglutination test. In other words, this test enables an answer to be given when the agglutination test is of no help, provided the skin test is done at the same time. Most English workers do not place the same faith in this test, which is little used in this country.

Blood-count

Information about the condition of the erythrocytes in this disease is surprisingly scanty. Hughes[53] says that "the red corpuscles diminish rapidly at first, from 5,000,000 to 3,000,000 per cubic millimetre (Bruce), more slowly but steadily later on throughout the pyrexial period, leading to the pronounced anæmia which so prolongs convalescence." Huddleson[52] does not mention either the red-cell count or the hæmoglobin content of these cells, but merely quotes Munger on the question of anisocytosis. Carpenter and Boak[17] describe a secondary anæmia with a hæmoglobin of 60–50%. Sordelli and Molinelli[67,85] found a hypochromic anæmia, becoming more marked during the course of the disease, in their Argentine cases. In my own series the necessary information was available in 221 cases (table x).

TABLE X—EVIDENCE REGARDING ANÆMIA IN 221 CASES OF UNDULANT FEVER

Cases with anæmia (less than 4 2 million red cells per c.mm.)			Cases without anæmia (4 2 million or more red cells per c.mm.)		
Normochromic (C.I. 0 9 – 1·1)	Hypochromic (C.I. less than 0 9)	Hyperchromic (C.I. more than 1·1)	Normochromic (C.I. 0 9 – 1·1)	Hypochromic (C.I. less than 0 9)	Hyperchromic (C.I. more than 1·1)
15	18	5	111	67	5
	38			183	

C.I. = colour index.

It will be seen that anæmia was present in 38 cases (17·2% of the 221 cases for which the necessary information was available) and that in 18 cases (47·4% of the cases of anæmia or 8·1% of the total) the anæmia was hypochromic.

The most frequently recorded feature of the white-cell count is a lymphocytosis, either absolute or relative.[17,19,60,71,86] Castañeda and Guerrero[19] found that in more than half their 888 cases there was an absolute lymphocytosis, whilst in more than a third the lymphocytosis was only relative. As regards the polymorphonuclear leucocytes, the absolute number was reduced only when there was a general leucopenia—a finding which they considered did not agree with the hypothesis of Munger and others that some brucella toxin had a selective destructive action on these cells. Table XI shows the evidence as regards lymphocytosis in the 394 cases in my own series in which a differential blood-count was done. It will be seen that of these 394 cases a lymphocytosis was present in 78·2%, but it was absolute in only 33 5% of the total cases (42 9% of those with lymphocytosis). In view of the suggestion by Burnet,[14] Osterlind,[73] Oakley et al.,[70] and others, that lymphocytes may synthesise antibodies, it seemed of interest to ascertain whether lymphocytosis, which has been shown to be so common a feature of undulant fever, was associated with a high agglutinin titre. Of the 132 cases with an absolute lymphocytosis 81 (61·4%) had an agglutinin titre of 1 in 1000 or more, whereas of the other 262 cases in which a differential cell-count was done, such an agglutinin titre was again present in 81 cases, representing only 30·9% of these 262 cases. So big a difference is at least suggestive.

TABLE XI—EVIDENCE OF LYMPHOCYTOSIS IN 394 CASES OF UNDULANT FEVER

Total no of cases with lymphocytosis (more than 30 % lymphocytes per c mm.) = 308		
No. of cases with *absolute* lymphocytosis (more than 3000 lymphocytes per c.mm.) = 132 (42 9 %)		No. of cases with only *relative* lymphocytosis
More than 3000 but less than 5000 lymphocytes per c mm.	More than 5000 lymphocytes per c.mm.	
102 (33·1 %)	30 (9 7 %)	176 (57·1 %)

As regards the alleged effect of brucella toxins in producing a polymorphonuclear leucopenia, the findings in this series are set out in table XII. Of the 394 cases for which the necessary information was available there was a polymorphonuclear leucopenia in 208 cases (52·8%) and in 150 of these (i.e., 72 1% of the cases with polymorphonuclear leucopenia or 38·1% of the total) this leucopenia was absolute.

Sordelli and Molinelli,[86] and later Molinelli[67] noted the disappearance of eosinophil leucocytes during the acute stages of the disease. In my own series the eosinophil leucocytes were absent in 224 of these 394 cases (56·9%), but in 14 there was an eosinophilia (more than 3% of eosinophils), in 6 of these the eosinophils amounting to more than 5%, and in 9 of the 14 the eosinophilia was absolute (more than 300 per c.mm.).

"CHRONIC BRUCELLOSIS"

A special diagnostic problem arises in connection with the condition described by American writers[39,40,41,56,60] as "chronic brucellosis." Many of these workers are convinced that in their own country a great deal of chronic ill health attributed to rheumatism, septic foci, neurosis, and other causes, is really due to unrecognised brucella infection. Many of these patients are free from fever and specific agglutinins are absent from their blood-serum. Our American friends admit freely that infection with brucella is often difficult to prove in such cases, but they point to the many recorded cases in which after years of illness and innumerable investigations brucella has eventually been grown from the blood. In most cases, however, no such conclusive evidence can be adduced, and the diagnosis rests on the combined results of the agglutination test, the opsonocytophagic test, the intradermal test, and the complement-fixation test. On such grounds it has been concluded that chronic brucellosis is extremely common in the United States, and I have already quoted an American estimate that 40,000–100,000 infections occur yearly.

Whilst regarding such estimates with extreme caution —or at any rate their application to this country—I think

TABLE XII—EVIDENCE OF POLYMORPHONUCLEAR LEUCOPENIA IN 394 CASES OF UNDULANT FEVER

Total no. of cases with polymorphonuclear leucopenia (less than 50 % of polymorphonuclear leucocytes per c.mm.) = 208		
No. of cases with *absolute* polymorphonuclear leucopenia (less than 3000 polymorphonuclear leucocytes per c.mm.) = 150		No. of cases with only *relative* polymorphonuclear leucopenia
Less than 3000 but more than 2000 p.l s per c.mm.	Less than 2000 p.l.s per c.mm.	
68	82	58

it is highly probable that many cases of chronic brucella infection are in our midst, for the reasons I have already adduced in support of an even higher incidence here than can be deduced from routine Widal testing—namely :

1. The known occurrence of many mild cases likely to elude diagnosis.
2. The isolation of brucella from cases with a persistently negative agglutination test, to which I would add
3. There is no doubt that brucella is hard to eradicate from the tissues in many cases, as is shown by the fact that
   - (a) relapses are very frequent, often after intervals of a year or more in which no apparent reinfection has occurred (Foshay[34] describes a case in which the injection of specific antigen for a skin test reactivated disease which had been quiescent for six years, with resultant disability for almost one year) ;
   - (b) the organism has often been isolated from the spleen, gall-bladder, lymph-glands, or bone-marrow ; and
   - (c) there is considerable evidence pointing to an intracellular habitat for this organism, giving it the protection enjoyed so conspicuously by many viruses.

Professor Debono, of Malta, lately told me of an interesting case which well illustrates the lurking habit of brucella.

A retired British colonel, who had had undulant fever in Malta as a subaltern thirty-five years previously, one day fell from his horse, fracturing his thigh. Though the fracture was accurately set, and there were no signs of local inflammation, his convalescence was complicated by a persistent fever. The patient insisted that his symptoms were exactly similar to those suffered by him in his attack of undulant fever thirty-five years before ; and, though his agglutination reaction was negative, *Br. melitensis* was eventually grown from his blood. Thus the organism had apparently hidden for all these years in the marrow of his femur, giving no sign of its presence and biding its time !

DIFFERENTIAL DIAGNOSIS

The extraordinary variety of the manifestations of this disease cause it to simulate a great many others ; and it is therefore not surprising to encounter a wealth of provisional diagnoses. In my series 97 different provisional diagnoses were made, in many cases several being employed successively. The commonest examples are shown in table XIII.

TABLE XIII—PROVISIONAL DIAGNOSES

Provisional diagnosis	*No. of times employed*
Influenza	63
(P.U.O.)	(63)
Paratyphoid	28
Tuberculosis	19
Malaria	13
Enteric fever	10
Pneumonia	8
Typhoid	8
Rheumatic fever	7
Rheumatism	6
Endocarditis (subacute bacterial)	5
Cholecystitis	4
Feverish cold	4
Gastritis	4

Some of the diagnoses less frequently employed indicated actual symptoms and complications of undulant fever rather than other ætiology (e.g., cholecystitis, bronchitis, laryngitis) ; but such attributions as Addison's disease, agranulocytosis, cerebrospinal meningitis, migraine, and appendicitis showed the wide range of symptoms and signs.

Let us briefly consider some of the diseases for which undulant fever is most often mistaken.

Influenza

Clinically the onset may be very much the same in both diseases, but in most cases the swinging temperature and heavy sweats, usually occurring at the same time every day, make a suspicion of undulant fever justifiable before long. Suggestive also may be the comparative absence of malaise during the afebrile intervals in undulant fever, in contrast to the feeling of illness which in influenza is so often far greater than the fever would make one expect.

Paratyphoid Fever

The resemblance here is, one would think, closer ; but digestive disturbances are much commoner in paratyphoid than in undulant fever. The temperature chart may not be so helpful as in influenza.

Typhoid Fever

Differentiation from typhoid fever is perhaps the most difficult of all, though not as difficult in England as in countries where the causative agent of undulant fever is *Br. melitensis* and cases of the "typhoid" type are therefore commoner. Hughes[53] gives as the chief distinguishing signs the intermittency and irregularity of the pyrexial curve in undulant fever, in contrast to the only occasional irregularities of the enteric temperature chart ; the much greater duration of the pyrexia in undulant fever ; and, during the first fortnight when differentiation is hardest, a temporary fall of temperature to nearly normal—an event most rare in typhoid in the absence of some special cause such as bleeding from the bowel. Help is also given by the profuse sweating and constipation, both so common in undulant fever ; the absence of "that tumid swollen condition of the abdomen, so common in enteric fever" ; the moist, swollen, and more uniformly furred tongue more commonly found in undulant fever ; and the greater swelling and tenderness of the spleen in the latter, the liver being also sometimes enlarged and tender. Joint affections when present are also helpful, for such complications are very rare, even in a slight degree, in enteric.

Tuberculosis

Long-continued and irregular fever with sweating are common to both diseases, and a troublesome non-productive cough is not infrequent in the early stages of undulant fever as in pulmonary tuberculosis. Characteristic undulations of the temperature curve occur sooner or later in most cases of undulant fever which last more than a fortnight, and loss of weight is much less common, less pronounced, and later in occurrence than in tuberculosis.

Malaria

Very few cases of indigenous malaria are seen in this country, but the disease may well be suspected in patients coming from abroad and especially members of the Forces who served during the war in the East and the Mediterranean area. In such cases undulant fever of the melitensis variety must be borne in mind. So far as clinical differentiation is concerned, Hughes is once again a valuable guide. He points out that undulant fever differs essentially from malaria in being non-paroxysmal, in having no periodical or regular apyrexial intervals, and in being unaffected by quinine to any great extent—and to this we may now add mepacrine and all the other new antimalarial drugs. But he admits that there may be some difficulty "in those cases in which there is a daily intermission, more especially when they occur in countries where ague also exists"—or of course in patients returning from such countries. Again "in undulant fever of an intermittent type the temperature rises so steadily and slowly that the patient often makes no complaint, or complains of but slight headache and general malaise. There is no paroxysm, and rarely any attempt at a rigor, though when the temperature falls profuse and continued sweating may take place." As we have seen, however, rigors are not very uncommon in cases in this country (328 in my series). Where malaria and undulant fever coexist, the malarial parasite will be found in the blood ; and if, when it has been driven therefrom by appropriate treatment, the fever still persists, undulant fever may reasonably be suspected.

Rheumatic Fever

This disease resembles undulant fever especially in those cases in which the onset is preceded by irregular pains in the joints, slight malaise, and sore throat. The ordinary febrile symptoms, such as anorexia, constipation, thirst, and chilliness, are common to the onset of both diseases. Moreover profuse sour-smelling sweats are also a feature of both and coincide in each case with remissions of the fever. In rheumatic fever, however, the anæmia is usually more pronounced and develops more rapidly, and the joint affections are more definite and painful (though in *Br. melitensis* infections this distinction is not always valid). The cardiac involvement almost universal in acute rheumatism is uncommon in undulant fever.

PROGNOSIS

Mortality

The case-mortality of undulant fever is low in all countries where it occurs. Hughes[53] gives it at about 2% for the Forces in Malta, and Huddleson[52] as 3% for his cases. In my series it was 2%, so that it cannot be regarded as a very lethal disease. On the other hand it is certainly the cause of much misery and loss of work, even if a conservative estimate of its incidence be accepted. Of my 19 fatal cases 5 had some other diseased condition unconnected with brucella infection, and 2 others were feeble and old (seventy and eighty-one).

Duration

As already pointed out, the incubation period is often difficult to assess owing to the insidious onset and the frequent history of weeks of ill health preceding the detection of definite fever or the onset of acute symptoms. Consequently an estimate of the duration of the illness in any given case must be provisional, especially as the final disappearance of fever is often followed by a long period of convalescence. For these reasons it seems best to define "duration" as total duration of the fever (so far as can be ascertained), reckoning from the believed date of onset of fever to its final termination, and therefore including any afebrile intervals which were not believed to be periods of complete freedom from infection (or invasion) followed by reinfection. On this basis the duration of my cases varied from a few days to forty-six years, and the distribution in convenient groups is shown in fig. 17.

It will be seen that in 204 cases (27·5%) the fever lasted less than four weeks, but that the duration in about half the cases (366) was between four and twelve weeks, whilst in 48 (6·5%) it was over six months and in 7 exceptional cases more than three years (viz., four years; more than four years; eight years; eleven to thirteen years; sixteen years; thirty-five years; and forty-six years).

Clinical Indications

In no disease is the termination of fever harder to foretell, but I have found the following indications useful. During a febrile period, the immediate precedence of a stretch of lower fever than has previously been experienced, the return of appetite, the disappearance of headache and sweating if formerly persistent, and the clearing of the tongue are all good signs. In an afebrile period the last two signs are also of good prognosis, and as the afebrile interval becomes much longer than previous such intervals the chances of the patient having got rid of this infection steadily improve. In some cases the patients complain of a peculiar taste in the mouth (or occasionally a smell in the nose) which is apparently so characteristic that 2 of my patients, who suffered from relapses or reinfection after intervals of six months and a year, knew instantly by this sign that undulant fever and no other illness was attacking them. In such cases, of course, the disappearance of this symptom is of good import.

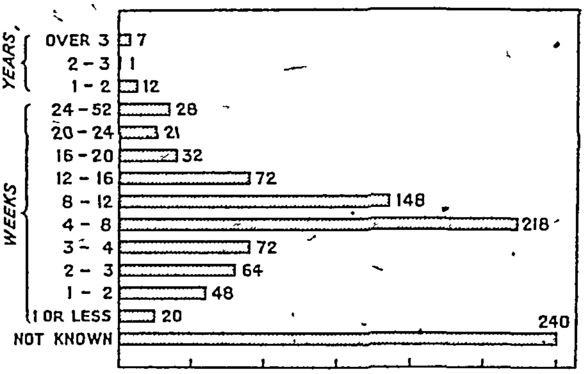

Fig. 17—Duration of fever in 743 cases of undulant fever.

Laboratory Indications

The laboratory is not particularly helpful in prognosis, but an increasing agglutination titre indicates that the body is building up resistance to the infection, and disappearance of anæmia with increase of leucocytes (particularly neutrophils), are also encouraging signs. On the other hand, in the absence of infection, agglutinins disappear from the blood far more quickly than they do in enteric fever, and an agglutination titre of 1 in 200 or more, found several months after the apparent recovery of the patient, may be a sign that relapse is on the way. In two instances where I warned practitioners of this, I received news of the relapse by return of post.

In a case reported by Dooley[25] a titre of 1 in 12,000 had dropped to 1 in 160 in five months and in another of his cases a drop occurred from 1 in 2560 to 1 in 80 in the same period. According to Olin[71] and Foshay[33] agglutinins may be present several years after recovery, but in such cases the infection may well be still present and the patient liable to relapse, as in Debono's case already mentioned.

Relapses and Reinfections

Relapses are certainly very common; but in any particular case it may be extremely difficult to say whether one is dealing with a true relapse or a reinfection. From the spleen, gall-bladder, or lymph-glands, the brucella may make a sortie after a long period of freedom from symptoms. It is this phenomenon which makes caution in prognosis advisable if we wish to avoid adding to the numerous disappointments caused by the fluctuations of the disease.

PROPHYLAXIS

Eradication of Contagious Abortion in Cattle

In a small and congested island such as ours, eradication of this disease presents great difficulty. It was hoped at one time that by means of the agglutination test and strict segregation of reacting animals a steady process of eradication within a reasonable time might be possible, as it had proved in parts of the United States and Canada. However, careful trials organised by an expert committee of the Agricultural Research Council, on which I served, showed that, under the conditions in this country, a herd from which infection is carefully weeded out, and which is protected from outside infection by every known means, will often become reinfected, usually within two years. Nothing is known for certain of the way in which such reinfection occurs, but conveyance of infection by birds and small mammals is an obvious possibility.

When this road was seen to be closed, recourse was had to vaccination of young animals with a live non-virulent vaccine. The American strain designated as "strain 19" (often abbreviated to S. 19 (fig. 18)) is being more and more widely employed by veterinarians for this purpose, and its use is reducing very considerably the degree of infection in herds, as well as saving many valuable animals to the dairy and meat industry by preventing abortion and sterility. There is no evidence that this living organism ever gives rise to virulent mutants, and it hardly ever gains access to the milk; so any such objection on public-health grounds has no validity. Moreover, since, as Stableforth has shown,[90] the agglutinins to which S.19 gives rise *in the calf* usually disappear at the time of the animal's first calving. S.19 vaccine can be used in conjunction with a policy of eradication.

Eradication by means of slaughter following an agglutination test is hardly a practical policy, owing to the high rate of infection of the cattle in this country. Such a policy, if thoroughly carried out, might reduce the present milk-supply of the country by a third.

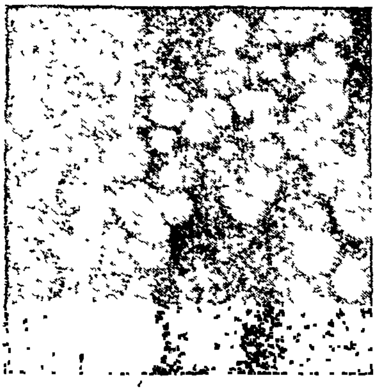

Fig. 18.—Colonies of *Br. abortus* strain 19; "going rough" (rough colonies show white).

Banning of Infected Milk-supplies

Though stopping the sale of milk containing brucella is an obvious way of protecting the public, and though section 25 of the Food and Drugs Act, 1938, makes it an offence for a person to sell, for human consumption, &c., the milk of any cow which to his knowledge is suffering from contagious abortion, yet the Ministries of Health and Agriculture take the view (which can only be confirmed or rejected by a decision of the courts) that the mere presence of agglutinins for brucella in the milk could not be regarded as proof of infection of the milk, for which purpose the presence of the actual organisms would need to be demonstrated before an offence could be proved. Moreover, even if the milk could be shown to be infected, it would still be necessary in any legal proceedings to establish that the owner knew that the cow in question was suffering from contagious abortion; and, though section 68 of the Act gives power to councils of counties and county boroughs to sample milk, there is no power to sample the cow's blood in order to carry out the agglutination test or to culture the organism. The legal position has, however, been improved by the issue of the Milk and Dairies Regulations, 1949, section 20 of which gives power to the medical officer of health of a sanitary district to stop a milk-supply, or to require its efficient heat treatment before sale, if he is satisfied that any person is suffering from a disease caused by consumption of such milk, or if he has reasonable grounds for suspecting that a person is so suffering or that the milk is infected with an organism capable of causing disease in man. As the milk-supplier is entitled to compensation under certain conditions laid down in the regulations, it is important that the medical officer of health should consider carefully the evidence of infection before taking action under these regulations, and consultation with a divisional (veterinary) inspector of the Ministry of Agriculture and Fisheries will often help him to make a wise decision.

Heat Treatment of Milk and Cream

Apart from the eradication of the disease in cattle and the taking of such precautions as are possible by laboratory workers, farm workers, veterinarians, &c., against infection by direct contact, the only prophylactic method of any value is the efficient heat treatment of all milk.

It is really astonishing how many people, many of whom should know better, continue to regard milk from [illegible] rom risk of conveying [illegible] such herds has caused many cases of undulant fever in this country and will continue to do so. Fortunately brucella is more easily killed by heat than the tubercle bacillus, and can be destroyed by simply raising the milk to boiling-point and then cooling it immediately. Commercial pasteurisation must, however, be our sheet-anchor, and the sooner it is extended so as to become universal, provided a high standard of performance is ensured, the sooner will the vast majority of the population of this country be free, to all intents and purposes from the danger of contracting this miserable, long-drawn-out, and occasionally fatal disease.

TREATMENT

Speaking generally, almost every conceivable remedy has been tried in this disease, including each new drug as it became fashionable. (I have records of 79 employed in my cases, excluding those used purely symptomatically.) Until quite lately by far the most effective treatment was protein shock, employing T.A.B. vaccine, but recently the new antibiotics have brought a ray of hope—first streptomycin, in conjunction with one of the sulphonamide drugs and more recently 'Aureomycin' and 'Chloromycetin' (chloramphenicol). Though the very limited experience so far obtained here with these antibiotics is distinctly encouraging, the frequency of relapses has shown that we still have much to learn about their employment and their limitations.

CONCLUSION

We should, I suggest, ask ourselves the following questions:

1. Are we so very sure that undulant fever is a rare disease in this country?
2. Do we always bear the possibility of this diagnosis in mind in cases of continued fever—or continued ill health without apparent fever—in which we are not completely satisfied that the case has been correctly labelled?
3. Do we, when we consider the possibility of undulant fever, always carry out the right diagnostic tests, or arrange for them to be done—and done *repeatedly*?
4. Do we order or allow milk which has not been efficiently heat-treated to be given to children, old people, mentally deficient, or mentally deranged patients, and other persons for whom we are responsible, thus exposing them to the danger of illness, perhaps long continued and distressing, or even death, from this disease?

Finally a word as to the future. Even if we succeed in getting the whole milk-supply pasteurised—because we cannot afford to wait for the complete eradication of the bovine disease—shall we have stamped out human undulant fever in Great Britain? Not so long as any of our cattle still suffer from contagious abortion, because there is always the danger of infection of humans by direct contact with infected animals. Admittedly the evidence of my large series of cases shows that infection by this means is comparatively uncommon. But apart from the missed cases, which may be numerous (most veterinarians doing cattle work seem to regard occasional malaise and rashes, which may be allergic, as part of their day's work) we must remember that there is no *Br. melitensis* infection (with the anomalous exceptions I have mentioned) or *Br. suis* infection in this country—at present. If such an invasion should occur, it will be not only cattle but sheep, goats, swine, and perhaps other domestic animals which will be affected, and consequently the chances of infection being conveyed to man will be greatly multiplied—the disease produced being usually more severe than that due to *Br. abortus*, with which alone we have to deal at present.

Is such a possibility fanciful? I do not think so. For example, nothing is known of the beginnings of undulant fever in the United States and the different varieties of brucella resemble each other so closely that it would be a bold man who would say that *Br. abortus* or *Br. suis* had not evolved from *Br. melitensis* or vice-versa.

Not being a veterinarian, I would not venture to suggest that the devoted efforts of our sister profession will not be successful in eradicating contagious abortion of cattle within a reasonable time: but I do note that in the United States the nation-wide campaign with this object does not seem to be meeting with as rapid and complete a success as had been hoped.

It seems to me, therefore, that it is the bounden duty of public authorities, the medical profession, and all enlightened people to do everything in their power firstly to protect milk-consumers by pasteurisation of the nation's milk-supply—including tuberculin-tested milk —and secondly to take all possible steps to diagnose this disease at an early stage, so that efficient treatment may be applied. Many years ago, when undulant fever was still believed to be confined to the Mediterranean area, Charles Nicolle used to tell his students that it was a disease of the future, and so it proved to be. But with your coöperation it may one day become a disease of the past.

I wish to express my deep indebtedness to all those medical practitioners, medical officers of health, and pathologists who have so kindly supplied me with material for these studies during the past twenty-one years; to all my friends in the veterinary profession who have supplied information and advice with regard to brucella infections of animals and especially to Dr. T. Dalling, chief veterinary officer, Ministry of Agriculture and Fisheries, Dr. A. Stableforth, deputy director, and other members of the staff of the Veterinary Laboratory, New Haw, Weybridge, who, amongst other kindnesses, have supplied me with three photographs reproduced in figs. 8, 9, and 18; to Sir Alexander Fleming for kindly sending me a photograph of Sir Almroth Wright; to the Commandant of the Royal Military Hospital, Millbank, for kindly supplying me with photographs of Sir David Bruce, Major Hughes, and Sir William Horrocks; to Professor Debono of Malta for kindly sending me the photograph of Sir Themistocles Zammit reproduced in fig. 5; and finally to innumerable friends in Malta, the United States of America, the Argentine, South Africa, Rhodesia, France, Denmark, Sweden, and other countries who have supplied me with most valuable information and comments.

"... In face of the mounting costs of therapy and our far from limitless resources we shall need to know not only how to reduce the incidence of disease, but also how to reduce it at a cost we can afford. It will always be impossible to make *every* improvement which has been demonstrated to be capable of bettering community health in some degree. ... We need to know, therefore, how to apportion our efforts for improving diet and housing, for relieving special stresses and strains or for trying to improve personal conduct. Indeed, the problem of defining the best possible use of available resources to yield the maximum benefit to the greatest number of people is now a central problem of community medicine.—Prof. FRED GRUNDY in a foreword to *Illness in Infancy*, by Dr. R. M. Dykes (Luton, 1950).

BACTERIAL SYNTHESIS OF VITAMIN B_{12} IN THE ALIMENTARY TRACT

THE existence of racial and familial hereditary factors determining the incidence of pernicious anæmia seems well established, but it is becoming generally recognised that a breakdown in the normal metabolism of an essential anti-pernicious-anæmia factor—vitamin B_{12}—is the primary cause of this condition. It is therefore important to consider the sources from which normal man and animals derive this vitamin.

Neither normal gastric juice nor beef muscle alone have any action in the treatment of pernicious anæmia, but the two materials fed together are effective, and so is raw liver. Thus it seemed likely, as Castle pointed out in 1930, that an extrinsic factor in food is acted on by an intrinsic factor in normal gastric juice to produce an anti-anæmia factor which is absorbed and stored in the liver; and that in pernicious anæmia there is a deficiency of the intrinsic factor.

It is well known that liver extracts are very much more active parenterally than by mouth (Gansslen 1930), and it has recently been shown that this is also true of vitamin B_{12}. The effective dose of vitamin B_{12} by mouth is 400 µg. per day (Spies et al. 1949), but when the vitamin is supplemented with normal gastric juice 5 µg. daily will suffice (Berk et al. 1948). The gastric juice must be fed not longer than 2 hours after the vitamin has been administered (Hall et al. 1949).

Vitamin B_{12} is identical with, or closely allied to, animal protein factor (Ott et al. 1948), cow-dung factor (Lillie et al. 1948), and extrinsic factor (Bethel et al. 1949). Generally speaking, vegetable foods such as grass, hay, &c., are low in this material, whether it is assayed as animal protein factor, extrinsic factor, or vitamin B_{12}.

The fæces of patients with pernicious anæmia show microbiological vitamin-B_{12} activity (Bethel et al. 1948), and extracts of them are clinically active when administered parenterally and behave similarly to vitamin B_{12} on paper chromatography (Callender et al. 1949).

Since pure vitamin B_{12} is highly effective if injected intramuscularly, when there is no possibility of its coming into contact with gastric juice, it does not seem necessary for this extrinsic factor to be changed by intrinsic factor before it can exert its effect. In-vitro formation of anti-anæmia principle from a mixture of gastric juice and beef has not been demonstrated (Formijne 1940).

EFFECT OF GASTRIC JUICE ON EXTRINSIC FACTOR IN VITRO

The following experiments were undertaken to ascertain whether the microbiological activity of the extrinsic factor in meat is increased by digestion with normal human gastric juice.

Minced lean beef was incubated at 37°C for 2½ hours with (1) water, (2) normal gastric juice, and (3) boiled normal gastric juice. After incubation all three preparations were boiled and filtered. The filtrates were assayed microbiologically, and at equivalent dilutions no difference was found between their growth-producing effects for either *Lactobacillus lactis* Dorner or *L. leishmannii*. Similar results were obtained when either minced veal or minced horsemeat were used as substrate.

VITAMIN B_{12} IN THE GUT OF MAN AND ANIMALS

Vitamin B_{12} (extrinsic factor) may be derived from the diet or be produced by bacterial synthesis in the gut. The vitamin B_{12} in the contents of the alimentary canal of a man, a horse, and a sheep was assayed. Samples were obtained at autopsy from various levels of the digestive tract, and suitable boiled extracts from these were assayed microbiologically using *L. leishmannii* as the test organism. The possible interference of desoxyribonucleosides was eliminated by making a further assay after heating the extracts to 100°C for 15 minutes in the presence of 0·2*N* NaOH, a procedure which completely destroys free vitamin B_{12} but is believed not to affect desoxyribonucleosides. The results of the various assays are given in table I.

The interpretation of these figures is complicated because they are the resultants of a number of factors. Intake of food and water, screening by pylorus and ileocæcal valve, dilution with gastric and intestinal juices, and dehydration by absorption through the intestinal wall all play a part, and at the same time vitamin B_{12} is probably being absorbed. Nevertheless, the results obtained present a clear picture of the distribution of vitamin B_{12} in the alimentary canal. Estimation of the lowest values is probably somewhat inaccurate owing to interference by non-specific factors, whereas for the high values the concentration of gut contents in the assay tube is very small, being of the order of 1 in 20,000, so that non-specific factors are diluted out.

The horse was fed on hay, proprietary rearing-nuts, bran, and straw, and the sheep on hay and nuts. The results of assays of these materials were as follows:

Feeding-stuff	*Total vitamin B_{12} (µg. per g. dry weight)*	*Alkali stable*
Hay	0·01	36%
Rearing-nuts	0·002	30%
Bran	0·002	50%
Straw	0·001	—

These values refer to dry and not to wet weight, as in the samples from the alimentary tract.

No explanation is offered for the high result obtained for the sheep's ileum. The similar proportion of alkali-stable activity in the stomach contents of the horse and in its diet is interesting. The ratio of alkali-stable to total activity is greater in the contents of the upper section of the alimentary canal than in the lower sections in all three subjects.

ISOLATION OF "VITAMIN B_{12}" FROM INTESTINAL CONTENTS

Samples of intestinal contents from horses were extracted, and after suitable purification, culminating in chromatographic separation, red fractions were obtained which, when dissolved in water and diluted to a colour comparable to that of a standard solution of crystalline

TABLE I—CONCENTRATION OF GROWTH FACTOR FOR *L. leishmannii* IN VARIOUS PORTIONS OF THE ALIMENTARY CANAL OF MAN, HORSE, AND SHEEP (µG. PER G. WET WEIGHT)

Part or organ	Man		Horse		Sheep	
	Total	Alkali-stable (%)	Total	Alkali-stable (%)	Total	Alkali-stable (%)
Rumen	..	..	..	..	0·35	1

vitamin B_{12}, had a similar growth-promoting activity for *L. lactis* Dorner and *L. leishmannii.*

Clinical Trials.

To confirm that the substance isolated from intestinal contents was indeed an anti-pernicious-anæmia factor, some of the purified fractions were applied to the treatment of typical cases of pernicious anæmia in relapse. The results of one such trial on 3 cases (table II) indicate that the material is clinically active when injected intramuscularly, and its activity approximates to that expected from its microbiological potency.

It appears, therefore, that the microbiologically active material in the horse's intestinal contents is similar in effect to crystalline vitamin B_{12}. Whether the two substances are completely identical is a subject for further investigation.

Trials are in progress to establish the minimum effective dose of the substance by mouth.

DISCUSSION

If the amount of vitamin B_{12} is a measure of anti-anæmic activity, our observations support the contention that normal gastric juice does not create anti-anæmia factor from extrinsic factor in food. An alternative possibility, that intrinsic factor is solely concerned with the adsorption of vitamin B_{12} is thus indirectly supported.

The vitamin-B_{12} content of the diet of the human subject was not known. In the horse the daily intake is only a minute fraction of the daily excretion, even assuming that all the alkali-labile growth-promoting activity in the diet is due to vitamin B_{12}. Synthesis must therefore take place in the horse's intestinal tract, and work now in progress indicates that certain strains of lactobacilli isolated from the intestinal contents are capable of producing considerable amounts of vitamin B_{12}.

The red fraction from the horse's intestinal contents is active both microbiologically and clinically; it is therefore similar to vitamin B_{12}. In view of the recent work on cow-dung factor (Winsten and Eigen 1949), however, this red material may not be completely identical with crystalline vitamin B_{12}.

In the animals examined, the amount of vitamin B_{12} synthesised in the intestine seemed to be considerable. In ruminants, synthesis occurs in both the upper and lower portions of the digestive tract, whereas in equines and man it apparently does not begin until the cæcum is reached. Broadly speaking, synthesis is greatest in ruminants, somewhat less in equines, and definitely less in man. Nevertheless, in man, when the absorptive mechanism is effective, it seems that intestinal synthesis contributes the major portion of the total amount of extrinsic factor. In vegetarians this must be the case.

If it is accepted that vitamin B_{12} is present in the lower reaches of the digestive tract, its absorption from this site remains to be explained. There are strong grounds for assuming that extrinsic factor, whether as crystalline vitamin B_{12} or in any other form, requires the presence of intrinsic factor before it can be assimilated. It is only recently that investigations have been made into the presence in the intestinal wall of intrinsic factor as distinct from extrinsic and intrinsic factor together. The presence of intrinsic factor in duodenal mucosa has been established (Bethel et al. 1949) and there is indirect evidence of its existence as far down as the wall of the ileum (Uotila 1936, 1938), but apparently its presence in the cæcum and colon has not been inquired into. It is generally assumed that a deficiency in intrinsic factor is the main characteristic of classical pernicious anæmia and that this deficiency is associated with a defect in the upper portion of the tract. How far down the defect exists is not certain, but if, as has been suggested, the argentaffine cells are concerned with the defect (Jacobson 1939), then the whole of the intestine, including the colon, is implicated. Man and non-ruminant animals are at a disadvantage in that autogenous vitamin B_{12} is not exposed to the absorptive area of their whole gastro-intestinal tract. This disadvantage is overcome in man by the inclusion of meat products in the diet and in animals by coprophagy, a common phenomenon well illustrated in the rabbit.

TABLE II—CLINICAL RESPONSE OF 3 CASES OF PERNICIOUS ANÆMIA IN RELAPSE TO INTRAMUSCULAR INJECTIONS OF VITAMIN-B_{12} CONCENTRATE PREPARED FROM HORSE'S INTESTINAL CONTENTS

In the past, consideration of the ætiology of macrocytic anæmia has been mainly directed to (*a*) the failure in intrinsic factor, (*b*) the dietary deficiency in extrinsic factor, and (*c*) possibly an abnormal expenditure of hæmopoietic factor. It is now suggested that a further factor should be taken into consideration—namely, the variations in intestinal vitamin-B_{12} content due to changes in intestinal conditions. The type and number of organisms present in the intestine will depend on the nature of the food residues. The bacterial flora produced by the cooked low-residue diet of western man would be expected to differ from that resulting from the high-residue diet of herbivora and vegetarians.

Microbiological assays of vitamin B_{12}, folic acid, and other essential factors in fæces might throw some light on the relationship between variations in diet and spontaneous remission and relapse in pernicious anæmia, and might explain the supposed value of strawberries in sprue, and bananas in cœliac disease.

SUMMARY

The vitamin B_{12} growth-promoting activity for *L. lactis* Dorner and *L. leishmannii* in meat is not increased by incubation with normal gastric juice.

The presence of vitamin B_{12} in the contents of the alimentary canal at various levels in man and animals is established and its amount is shown to be greatest below the ileocæcal valve.

Purified extracts made from intestinal contents are shown to be active in the treatment of pernicious anæmia when given parenterally.

It is suggested that in man the normal requirements of vitamin B_{12} are met by bacterial synthesis in the colon.

BACTERIAL SYNTHESIS OF VITAMIN B_{12} IN THE ALIMENTARY TRACT

THE existence of racial and familial hereditary factors determining the incidence of pernicious anæmia seems well established, but it is becoming generally recognised that a breakdown in the normal metabolism of an essential anti-pernicious-anæmia factor—vitamin B_{12}—is the primary cause of this condition. It is therefore important to consider the sources from which normal man and animals derive this vitamin.

Neither normal gastric juice nor beef muscle alone have any action in the treatment of pernicious anæmia, but the two materials fed together are effective, and so is raw liver. Thus it seemed likely, as Castle pointed out in 1930, that an extrinsic factor in food is acted on by an intrinsic factor in normal gastric juice to produce an anti-anæmia factor which is absorbed and stored in the liver; and that in pernicious anæmia there is a deficiency of the intrinsic factor.

It is well known that liver extracts are very much more active parenterally than by mouth (Gansslen 1930), and it has recently been shown that this is also true of vitamin B_{12}. The effective dose of vitamin B_{12} by mouth is 400 µg. per day (Spies et al. 1949), but when the vitamin is supplemented with normal gastric juice 5 µg. daily will suffice (Berk et al. 1948). The gastric juice must be fed not longer than 2 hours after the vitamin has been administered (Hall et al. 1949).

Vitamin B_{12} is identical with, or closely allied to, animal protein factor (Ott et al. 1948), cow-dung factor (Lillie et al. 1948), and extrinsic factor (Bethel et al. 1949). Generally speaking, vegetable foods such as grass, hay, &c., are low in this material, whether it is assayed as animal protein factor, extrinsic factor, or vitamin B_{12}.

The fæces of patients with pernicious anæmia show microbiological vitamin-B_{12} activity (Bethel et al. 1948), and extracts of them are clinically active when administered parenterally and behave similarly to vitamin B_{12} on paper chromatography (Callender et al. 1949).

Since pure vitamin B_{12} is highly effective if injected intramuscularly, when there is no possibility of its coming into contact with gastric juice, it does not seem necessary for this extrinsic factor to be changed by intrinsic factor before it can exert its effect. In-vitro formation of anti-anæmia principle from a mixture of gastric juice and beef has not been demonstrated (Formijne 1940).

EFFECT OF GASTRIC JUICE ON EXTRINSIC FACTOR IN VITRO

The following experiments were undertaken to ascertain whether the microbiological activity of the extrinsic factor in meat is increased by digestion with normal human gastric juice.

Minced lean beef was incubated at 37°C for $2^1/_2$ hours with (1) water, (2) normal gastric juice, and (3) boiled normal gastric juice. After incubation all three preparations were boiled and filtered. The filtrates were assayed microbiologically, and at equivalent dilutions no difference was found between their growth-producing effects for either *Lactobacillus lactis* Dorner or *L. leishmannii*. Similar results were obtained when either minced veal or minced horsemeat were used as substrate.

VITAMIN B_{12} IN THE GUT OF MAN AND ANIMALS

Vitamin B_{12} (extrinsic factor) may be derived from the diet or be produced by bacterial synthesis in the gut. The vitamin B_{12} in the contents of the alimentary canal of a man, a horse, and a sheep was assayed. Samples were obtained at autopsy from various levels of the digestive tract, and suitable boiled extracts from these were assayed microbiologically using *L. leishmannii* as the test organism. The possible interference of desoxyribonucleosides was eliminated by making a further assay after heating the extracts to 100°C for 15 minutes in the presence of 0·2*N* NaOH, a procedure which completely destroys free vitamin B_{12} but is believed not to affect desoxyribonucleosides. The results of the various assays are given in table I.

The interpretation of these figures is complicated because they are the resultants of a number of factors. Intake of food and water, screening by pylorus and ileocæcal valve, dilution with gastric and intestinal juices, and dehydration by absorption through the intestinal wall all play a part, and at the same time vitamin B_{12} is probably being absorbed. Nevertheless, the results obtained present a clear picture of the distribution of vitamin B_{12} in the alimentary canal. Estimation of the lowest values is probably somewhat inaccurate owing to interference by non-specific factors, whereas for the high values the concentration of gut contents in the assay tube is very small, being of the order of 1 in 20,000, so that non-specific factors are diluted out.

The horse was fed on hay, proprietary rearing-nuts, bran, and straw, and the sheep on hay and nuts. The results of assays of these materials were as follows:

Feeding-stuff					*Total vitamin B_{12} (µg. per g. dry weight)*	*Alkali-stable*
Hay	..	..	..	..	0·01	36%
Rearing-nuts	..	..	..		0·002	30%
Bran	..	..	..	..	0·002	50%
Straw	..	..	..	..	0·001	—

These values refer to dry and not to wet weight, as in the samples from the alimentary tract.

No explanation is offered for the high result obtained for the sheep's ileum. The similar proportion of alkali-stable activity in the stomach contents of the horse and in its diet is interesting. The ratio of alkali-stable to total activity is greater in the contents of the upper section of the alimentary canal than in the lower sections in all three subjects.

ISOLATION OF "VITAMIN B_{12}" FROM INTESTINAL CONTENTS

Samples of intestinal contents from horses were extracted, and after suitable purification, culminating in chromatographic separation, red fractions were obtained which, when dissolved in water and diluted to a colour comparable to that of a standard solution of crystalline

—and of the hydrogenated alkaloids of ergot were investigated. The drugs were either injected directly into the mucosa of the bowel or given as an intravenous infusion.

For the intravenous procedure a needle was inserted into a suitable vein in the right forearm and connected to a constant speed infusion apparatus. A steady infusion of saline was started, and the blood-pressure was measured by the auscultatory method from the left arm. When basal readings had been obtained, the saline infusion was superseded by one containing the drug under investigation.

When the direct effect of the substance was to be studied, it was dissolved in 0·5 ml. of physiological saline and injected into the bowel close to the thermocouple. If the drug seemed to produce a rise in the temperature of the bowel, the subsequent experiments consisted in injecting 0·5 ml. of physiological saline at 25°C as a control and then, after an interval, injecting the drug dissolved in 0·5 ml. of saline at 25°C. If a constrictor response appeared likely, saline at 35°C was used. Thus anomalous responses due to the temperature of the saline could be eliminated.

RESULTS WITH ADRENALINE AND NORADRENALINE

For these experiments *l*-adrenaline tartrate and *l*-noradrenaline hydrochloride were used.

Intravenous Infusions.—Seven experiments in which adrenaline was infused and six in which noradrenaline was infused were made. Doses of 5–10 µg. per minute were infused for 2–5 minutes. The response of the colon seemed to be similar in all experiments. Shortly after the start of the infusion there was a rapid fall in bowel temperature of 0·9–1·5°C. This lowered temperature was maintained for periods up to 2 minutes after the infusion had been discontinued. The temperature then returned to the level observed before the infusion. The responses of the blood-pressure and heart-rate were found to be similar to results previously reported for adrenaline (Gordon and Levitt 1935) and noradrenaline (Goldenberg et al. 1948, Swan 1949a). Fig. 1 shows the effect of intravenous adrenaline and fig. 2 that of intravenous noradrenaline. In some experiments the temperature-level tended, after the infusion, to rise transiently above the base-line. This effect had the same time relationship as the dilatation which occurs in the hand after adrenaline infusions (Swan 1949b).

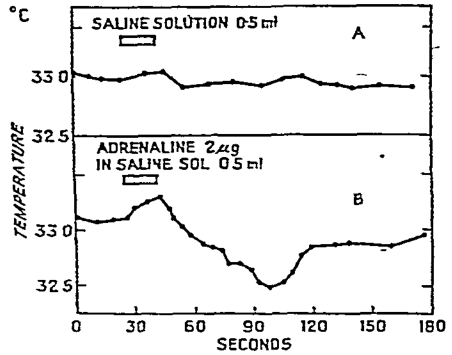

Fig. 3—Effect of local infiltration of bowel on bowel temperature: A, control (physiological saline solution at 35°C); B, adrenaline 2 µg. in 0·5 ml. of physiological saline solution at 35°C.

Local injections of adrenaline or of noradrenaline produced a sustained fall in colostomy temperature in four patients. A control injection of 0·5 ml. of warm saline (35°C) was made into the bowel wall, and 5 minutes later adrenaline 2 µg. dissolved in 0·5 ml. of warm saline was injected (fig. 3).

RESULTS WITH DIHYDROERGOCORNINE AND HYDERGINE

The action of dihydroergocornine and 'Hydergine'* on blood-flow in skin and muscle has been investigated by Barcroft et al. (1950).

Intravenous infusion with either hydergine or dihydroergocornine produced a fall in bowel temperature lasting about 30 minutes. A typical experiment is shown in fig. 4, in which the relation of the fall in colostomy temperature to the rise in finger temperature is clearly seen. Five experiments were performed on five patients with normal blood-pressure, and the effect on two patients with raised blood-pressure was also observed. Hydergine was given to five patients in doses of 0·1–0·5 mg. intravenously, and dihydroergocornine 0·5 mg. was given to each of two patients. The fall in bowel temperature occurred in all cases and usually began about 5–10 minutes after the infusion of the ergot alkaloid was complete. A fall in tissue temperature of up to 2·3°C was observed. The fall was greater with the larger doses of the alkaloids. The duration of infusion of the drug, which varied from 1$^1/_2$ to 10 minutes, made no apparent difference to the response obtained. In the two hypertensive patients the blood-pressure fell but the bowel temperature continued to fall for some time after the lowest blood-pressure was recorded.

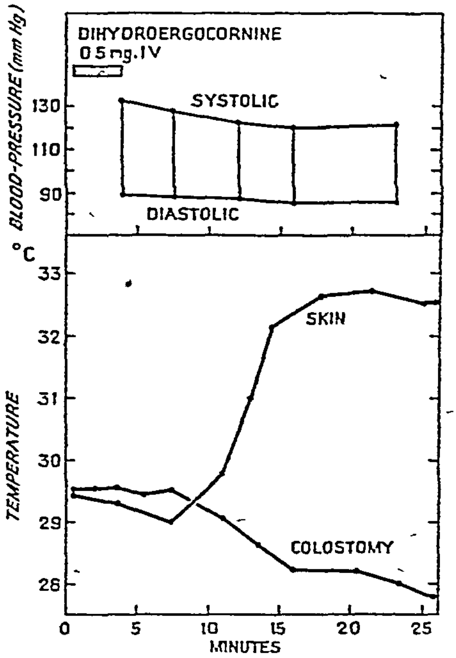

Fig. 4—Effect of intravenous dihydroergocornine 0·5 mg on temperature of colostomy tissue, skin temperature of right index finger, and blood-pressure.

Local infiltration of dihydroergocornine into the bowel produced a different response from that of intravenous infusion. The tissue temperature rose 1·1–1·5°C in each of these patients and returned to the initial level in 15–20 minutes (fig. 5).

DISCUSSION

Adrenaline and Noradrenaline

These two sympathomimetic amines, whether given intravenously or locally, invariably produced a fall in colostomy temperature in our subjects. We therefore conclude that the fall in tissue temperature was due to diminution in the flow of blood through the exposed bowel. This effect is considered to be a local constrictor response of the colonic blood-vessels, since it occurred when the adrenaline or noradrenaline was infiltrated

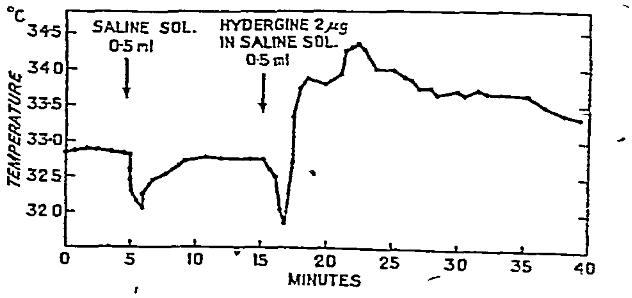

Fig. 5—Effect of local infiltration of bowel on bowel temperature: A, control (physiological saline solution at 25°C); B, hydergine 2 µg. in physiological saline solution 0·5 ml. at 25°C.

---

* Hydergine (Sandoz) is a mixture, in equal amounts, of dihydroergocornine, dihydroergokryptine, and dihydroergocristine.

Some advantage is undoubtedly to be gained by supplementing this with foodstuffs rich in vitamin B_{12}.

We wish to thank Dr. A. J. McCall, Dr. J. G. A. McSorley, Mr. R. S. Roberts, and Prof. H. L. Sheehan for their help in the investigation.

ACTION OF ADRENALINE, NORADRENALINE, AND DIHYDROERGOCORNINE ON THE COLONIC CIRCULATION

J. GRAYSON
M.D., M.Sc. Manc.
LECTURER IN PHYSIOLOGY, UNIVERSITY OF BRISTOL

H. J. C. SWAN
M.B. Lond., M.R.C.P.
LECTURER IN PHYSIOLOGY, ST. THOMAS'S HOSPITAL MEDICAL SCHOOL, LONDON

STUDIES of vascular reactions in the splanchnic area are necessarily confined largely to experiments on animals, and conclusions drawn from such experiments are not always applicable to man, for anæsthesia, surgical manipulation, and hæmorrhage may affect the experimental findings, and what is true of one species is not always true of another. Nevertheless, in the last few years experimental procedures have given us some valuable information concerning hepatic (Bradley et al. 1945) and renal (Goldring et al. 1940) blood-flow in man. We describe here a simple method whereby further information concerning the circulation in the splanchnic area may be obtained by measuring the temperature changes in bowel exteriorised at operation. The effects of some pharmacological substances on the colonic circulation have been studied in this way.

METHOD

If the temperatures of the blood and environment are constant but unequal, the temperature of any tissue will depend on the blood-flow through the tissue. This general principle can be applied as an index of changes in blood-flow. In man it has been used in the assessment of circulatory phenomena in skin by Parmenter and Benedict (1929) and in muscle by Barcroft and Millen (1939). A somewhat similar method has recently been applied by one of us (Grayson 1949) in recording continuously the changes in temperature in the mucosa and muscle layer of the exposed bowel in patients with an ileostomy or colostomy. The experimental procedure was as follows:

The patient lies still for about 30 minutes with the colostomy exposed, in a room which is kept at a constant temperature of about 21°C throughout the experiment. A fine needle thermocouple is then inserted into the mucosa or into the muscular layer of the exposed bowel, and the leads are connected through a suitable circuit to a sensitive galvanometer which measures changes in tissue temperature of the order of 0·02°C. A manually operated mechanical device is used to obtain a continuous record on a kymograph (Schmidt and Pierson 1934). The detailed technique, including construction of the thermocouples and estimations of the normal rate of cooling in the bowel, has been described elsewhere (Grayson 1949).

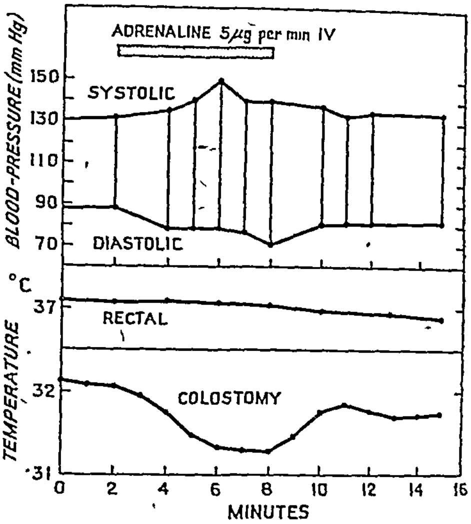

Fig. 1—Effect of intravenous infusion of adrenaline 5 µg. per minute on rectal temperature, blood-pressure, and colostomy temperature.

This method, though simple in principle and practice and completely innocuous to the patient, has limitations. First, the choice of subjects is small, and most of those available are in late middle life, often in poor physical condition. Secondly, the response obtained is qualitative only. Unpublished experiments made by one of us (J. G.) show that the relation between tissue temperature and blood-flow is not linear, and without previous knowledge of the initial blood-flow and the behaviour of the tissue under investigation it is impossible to assess changes of temperature in terms of absolute blood-flow. Thirdly, the information obtainable concerns only the mucosa or muscle wall of the part exposed, and it is not possible to study changes of blood-flow in the mesentery, omentum, or other viscera in this way.

However, the responses in many different parts of the bowel may be obtained by selecting suitable subjects—patients with ileostomy, cæcostomy, or the various types of colostomy.

In the observations reported here the effects of two sympathomimetic amines—adrenaline and noradrenaline

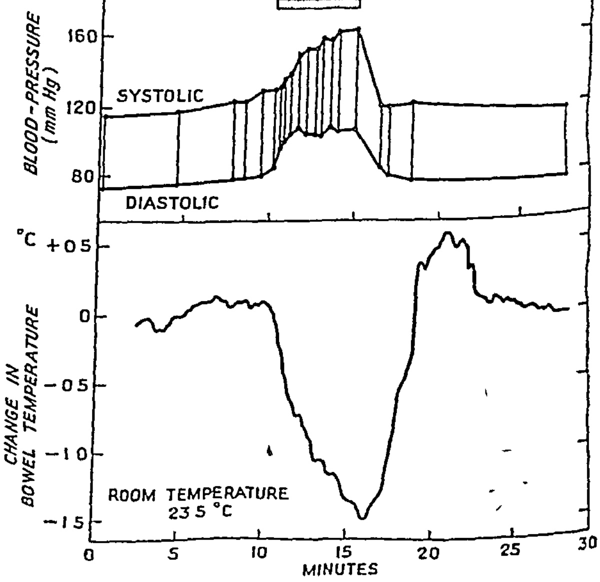

Fig. 2—Effect of intravenous infusion of noradrenaline 10 µg. per minute on colostomy temperature and blood-pressure.

—and of the hydrogenated alkaloids of ergot were investigated. The drugs were either injected directly into the mucosa of the bowel or given as an intravenous infusion.

For the intravenous procedure a needle was inserted into a suitable vein in the right forearm and connected to a constant speed infusion apparatus. A steady infusion of saline was started, and the blood-pressure was measured by the auscultatory method from the left arm. When basal readings had been obtained, the saline infusion was superseded by one containing the drug under investigation.

When the direct effect of the substance was to be studied, it was dissolved in 0 5 ml. of physiological saline and injected into the bowel close to the thermocouple. If the drug seemed to produce a rise in the temperature of the bowel, the subsequent experiments consisted in injecting 0·5 ml. of physiological saline at 25°C as a control and then, after an interval, injecting the drug dissolved in 0 5 ml. of saline at 25°C. If a constrictor response appeared likely, saline at 35°C was used. Thus anomalous responses due to the temperature of the saline could be eliminated.

RESULTS WITH ADRENALINE AND NORADRENALINE

For these experiments l-adrenaline tartrate and *l*-noradrenaline hydrochloride were used.

Intravenous Infusions.—Seven experiments in which adrenaline was infused and six in which noradrenaline was infused were made. Doses of 5–10 µg. per minute were infused for 2–5 minutes. The response of the colon seemed to be similar in all experiments. Shortly after the start of the infusion there was a rapid fall in bowel temperature of 0 9–1·5°C. This lowered temperature was maintained for periods up to 2 minutes after the infusion had been discontinued. The temperature then returned to the level observed before the infusion. The responses of the blood-pressure and heart-rate were found to be similar to results previously reported for adrenaline (Gordon and Levitt 1935) and noradrenaline (Goldenberg et al. 1948, Swan 1949a). Fig. 1 shows the effect of intravenous adrenaline and fig. 2 that of intravenous noradrenaline. In some experiments the temperature level tended, after the infusion, to rise transiently above the base-line. This effect had the same time relationship as the dilatation which occurs in the hand after adrenaline infusions (Swan 1949b).

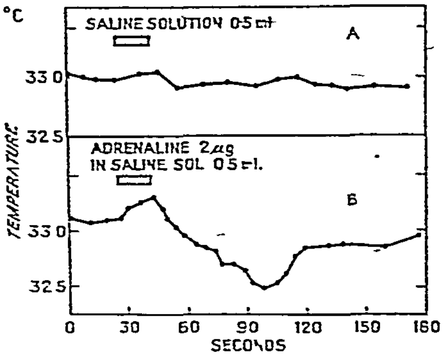

Fig. 3—Effect of local infiltration of bowel on bowel temperature: A, control (physiological saline solution at 35°C); B, adrenaline 2 µg. in 0 5 ml. of physiological saline solution at 35°C.

Local injections of adrenaline or of noradrenaline produced a sustained fall in colostomy temperature in four patients. A control injection of 0·5 ml. of warm saline (35°C) was made into the bowel wall, and 5 minutes later adrenaline 2 µg. dissolved in 0 5 ml. of warm saline was injected (fig. 3).

RESULTS WITH DIHYDROERGOCORNINE AND HYDERGINE

The action of dihydroergocornine and 'Hydergine'* on blood-flow in skin and muscle has been investigated by Barcroft et al. (1950).

Intravenous infusion with either hydergine or dihydroergocornine produced a fall in bowel temperature lasting about 30 minutes. A typical experiment is shown in fig. 4, in which the relation of the fall in colostomy temperature to the rise in finger temperature is clearly seen. Five experiments were performed on five patients with normal blood-pressure, and the effect on two patients with raised blood-pressure was also observed. Hydergine was given to five patients in doses of 0·1–0 5 mg. intravenously, and dihydroergocornine 0 5 mg. was given to each of two patients. The fall in bowel temperature occurred in all cases and usually began about 5–10 minutes after the infusion of the ergot alkaloid was complete. A fall in tissue temperature of up to 2·3°C was observed. The fall was greater with the larger doses of the alkaloids. The duration of infusion of the drug, which varied from 1½ to 10 minutes, made no apparent difference to the response obtained. In the two hypertensive patients the blood-pressure fell but the bowel temperature continued to fall for some time after the lowest blood-pressure was recorded.

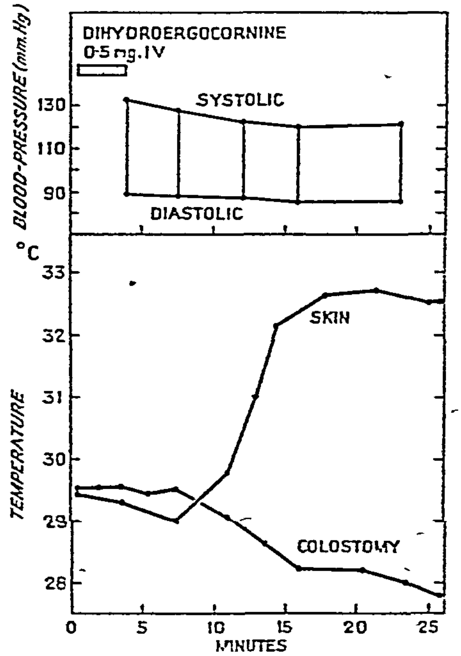

Fig. 4—Effect of intravenous dihydroergocornine 0 5 mg. on temperature of colostomy tissue, skin temperature of right index finger, and blood-pressure.

Local infiltration of dihydroergocornine into the bowel produced a different response from that of intravenous infusion. The tissue temperature rose 1·1–1 5°C in each of these patients and returned to the initial level in 15–20 minutes (fig. 5).

DISCUSSION

Adrenaline and Noradrenaline

These two sympathomimetic amines, whether given intravenously or locally, invariably produced a fall in colostomy temperature in our subjects. We therefore conclude that the fall in tissue temperature was due to diminution in the flow of blood through the exposed bowel. This effect is considered to be a local constrictor response of the colonic blood-vessels, since it occurred when the adrenaline or noradrenaline was infiltrated

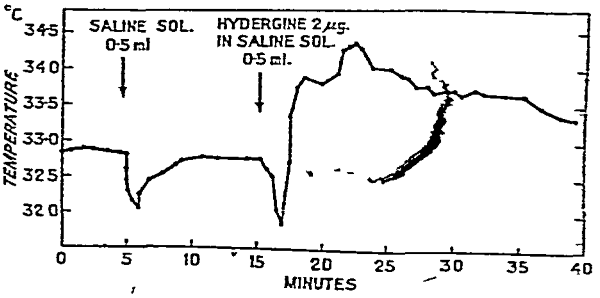

Fig. 5—Effect of local infiltration of bowel on bowel temperature: A, control (physiological saline solution at 25°C); B, hydergine 2 µg. in physiological saline solution 0 5 ml. at 25°C.

---

* Hydergine (Sandoz) is a mixture, in equal amounts, of dihydroergocornine, dihydroergokryptine, and dihydroergocristine.

directly into the bowel wall. When the drug was given intravenously the fall in colostomy temperature coincided with the rise in blood-pressure; so an active vasoconstriction must have taken place.

Hydrogenated Alkaloids of Ergot

We have observed a fall in temperature in all the subjects given an intravenous infusion of dihydroergocornine or hydergine. Since this occurred in some subjects without any fall in blood-pressure, we conclude that it is the result of an active vasoconstriction. Wilkins et al. (1949) have observed a fall in renal and hepatic blood-flows on intravenous injection of dihydroergocornine. Our observation suggests a comparable reaction in another part of the splanchnic area. This vasoconstriction in the colonic circulation may be due either to a direct constrictor action on the vessels or to a nervous constrictor mechanism. Since the local injection of dihydroergocornine causes a rise in bowel temperature, we conclude that the direct effect of the alkaloids on the vessels is dilator. The constrictor response seen on intravenous injection without any fall in blood-pressure is therefore due to a nervous reflex which overrides the local direct effect. It is unlikely that the alkaloids cause an outpouring of humoral constrictor substances, since one of us (H. J. C. S.) has observed consistent dilatation in the skin on infusion of the dihydro alkaloids.

Thus the over-all response of the colonic circulation to the dihydro alkaloids of ergot is vasoconstrictor and probably reflex. This may well be another example of the reciprocal relation between bowel and skin circulations which has been shown to exist (Grayson 1949).

Bluntschli and Goetz (1947) concluded that a reflex splanchnic vasodilatation was responsible for the fall in blood-pressure on intravenous infusion with dihydroergocornine. They observed that in hypertensive patients a considerable and sustained fall in blood-pressure occurred on administration of 0·3 mg. of dihydroergocornine. After splanchnic sympathectomy, however, this response was absent or much reduced. We may point out, however, that in these circumstances a moderate fall in blood-pressure had already taken place as a result of the operation. Hayes et al. (1949) and Barcroft et al. (1950), using a similar dosage, find little fall in blood-pressure in persons with normal blood-pressure.

SUMMARY

A simple method is described whereby the changes in temperature of the human colon exposed at colostomy can be used as a qualitative index of blood-flow change in the colon.

By this method it is shown that adrenaline and noradrenaline cause a vasoconstriction. The dihydrogenated alkaloids of ergot cause a reflex vasoconstriction, but their direct action on the vessels is dilatation.

We would like to express our gratitude to Prof. H. Barcroft, at whose suggestion this investigation was undertaken. Some of the expenses were defrayed by the Colston Research Fund and by the Medical Research Council.

TECHNIQUE OF
DIAGNOSTIC CHEST FLUOROSCOPY

STEPHEN HALL
M.A., M.B. Camb., M.R.C.P.
CHEST CONSULTANT, BUCKS COUNTY COUNCIL; PHYSICIAN, ROYAL BUCKS HOSPITAL, AYLESBURY

WILLIAM TATTERSALL
M.A., M.D. Camb.
CHEST PHYSICIAN, READING

From the Chest Service of the Oxford Regional Hospital Board

NEXT to taking a careful history, fluoroscopy probably gives more valuable information than any other single procedure in the diagnosis of chest disease. Also it is cheap, rapid, and safe.

Hall (1942) screened 1370 factory workers and found the same incidence of pulmonary tuberculosis as was later found by mass radiography for such a population. Tattersall (1948), reviewing 2908 cases fluoroscoped at a chest clinic, found no reason to believe that any cases of tuberculosis had been missed by this method.

APPARATUS

Various suitable apparatus is available. There must be ample room between the fluorescent screen and the tube to tilt and move the patient freely. For this reason some of the large X-ray sets are not very satisfactory when they have to be used with the table placed vertically just behind the patient. A Levy-West screen gives the best fluorescent image.

The examination should be conducted with 5 mA. and 80 kV. This degree of penetration should enable the whole examination to be made within 60 seconds; with less, the examination may take longer and expose the patient to heavier irradiation in the long run. Less penetration can, however, be used for children and very thin adults. A foot-switch which simultaneously turns off the red light and turns on the X-ray beam facilitates minimal irradiation; it is more convenient than to rely on an assistant to turn off the light.

PRECAUTIONS

The risks from *cumulative exposure* to X rays have been fully described, and anyone doing any sort of X-ray work must take the recognised and effective precautions. When the more precise and detailed help of a skilled physicist is not immediately available, arrangements can be made with the National Physics Laboratory to test quantitatively an operator's degree of exposure to irradiation.

We have not been able to discover any report of X-ray trauma to a patient from chest fluoroscopy.

The most common source of error in fluoroscopy arises from inadequate *dark adaptation*. If one depends on sitting in a darkened room before starting work, patience will eventually flag, and sooner or later errors will be made as a result of starting to screen prematurely. A better plan is to wear well-fitting dark spectacles, with side protection, for at least half an hour before screening. (A cheap pair of sun-glasses is useless.) Further, as the eyes become accommodated during this time, adaptation can be further improved by having a pair of clip-on dark glasses, so that, for the last ten minutes or so before starting the operator is looking through two layers of dark glass. This routine enables other work to be done while the visual purple is being mobilised.

All apparatus should be *shock-proof*.

THE EXAMINATION

The procedure consists in watching the lung fields in the postero-anterior view, the antero-posterior view, and with all degrees of tilting, leaning, and twisting from these positions, while the patient breathes deeply, or "pants as if running a race." The cardiac shadow is observed in the three classical positions. It is well to be prepared to examine the œsophagus by a barium swallow.

Obviously, all the ordinary radiographic abnormalities are looked for, and they should be readily seen. This paper deals only with abnormalities which may be missed in a "straight" film but detected fluoroscopically, and with pitfalls in fluoroscopic diagnosis. The essential feature of the technique is that the lung fields are examined dynamically during accentuated ventilation. By moving the patient about all the time, the depth of various shadows can be estimated by parallax, while forward and backward tilting at the same time permits careful scrutiny of tissue otherwise concealed by the ribs. Thus fluoroscopy differs from inspection of X-ray films just as cinephotography differs from still photography.

Parallax readily discloses extrathoracic shadows. Increased striate shadows in a lower zone can often thus be assigned to the breast (especially of a nursing mother) as well as by lifting the breast. Similarly, parallax should always avert the "pig-tail" pitfall and localise calcification in costal cartilages, as well as the position of shrapnel or other foreign bodies.

As the patient is tilted obliquely, a fluid level is sometimes definitely seen in an otherwise doubtful cavity not suspected from the straight film, which prompts tomographic confirmation.

It is sometimes suggested that the soft hazy shadow associated with early tuberculosis may be missed if no film is taken. If the patient is screened only in a stationary position this may be so, but if each part of the lung fields is examined from as many aspects as possible, attention will often be called to such shadows by their change in shape and density as the patient is twisted and turned. The shadows least easily detected are the small fine mottled opacities of disseminated lesions (miliary tuberculosis, pneumoconiosis) which are equally difficult to discern in all planes, whether they are localised or occur throughout the lungs. The same difficulty, however, may arise in assessing fine mottling in a straight film. The association of rather horizontal ribs with a relative increase of lung translucency—most readily observed during vigorous expiration—suggests emphysema. The hemidiaphragm of the emphysematous side is often depressed and has a reduced range of movement.

When a bronchus is obstructed, the lighting up of the affected lung field may be altered. If the obstruction is partial, air may be able to enter the distal bronchial tree but not escape—the phenomenon described as "trapping." In this case, during expiration, the segment of lung involved remains lit up as the translucency of the normal lung field diminishes—an appearance which at once calls for further elucidation. In the early stage of collapse, aeration of the collapsing segment is impeded, and it will light up less rapidly than the normal field during inspiration, and look hazy during this phase.

Segmental collapse can often be located by parallax and tilting. This is especially true of right-middle-lobe collapse, which shows as a sharply defined wedge-shaped opacity as the patient is tilted backwards. Such a diagnosis has sometimes been made with certainty, only to find that on photography the lesion could not be demonstrated because the exact degree of lordotic tilt necessary had not been attained in the film. Tilting is particularly necessary to pick up collapse of the anterior segment; the lateral segment often exhibits the well-known fan-shaped haze which can be seen in the vertical position. Much the same comments apply to the lingula on the left side, though this wedge is not so sharply defined.

Interlobar septa, especially if distorted, are more oft seen fluoroscopically than in a postero-anterior fil and by their distortion they may indicate contracti of a lobe. When discovered as the sharp edge of a obvious opacity which appears to have a hazy edge in t "straight" view, the finding is particularly useful.

Special care must be taken with the scrutiny of t lung apices, which normally light up less than t bases on ventilation. It is important to examine the postero-anteriorly, and antero-posteriorly, with t patient tilted back and forwards as far as practicable.

It is said that mediastinal shift on inspiration can noted when there is pulmonary collapse. Mediastin shift on ventilation is related more particularly to t rigidity of the mediastinum and is not of great diagnost value (except of course in the management of pneumothorax).

It is not generally realised how well the posteri mediastinum, and especially the trachea, can be di played in the right anterior oblique position. Starti with the epiglottis, which is a good landmark, t trachea can be followed, in all but the most obese subject right down to the bifurcation, together with the fir inch of both main bronchi. In children this examinatio is most valuable and often an enlarged bifurcatio gland may be easily seen.

The costophrenic angles are best seen in the anter posterior view with the patient tilted forwards an rotated a little until, in the normal subject, the diaphrag is seen originating from the lower ribs at a sharp angl This position also gives the best view of the posteri lung bases, lying behind and below the dome of th diaphragm.

Total or partial paralysis of a hemidiaphragm is a important condition not readily revealed by a chest fil Diaphragmatic movement can be accentuated by askin the patient to sniff. Paralysis of the phrenic nerve caused not only by neoplasms but also by inflammator conditions, and it may be relatively transient. In case where no cause has been found it has possibly been due t occlusion of the phrenic nerve by calcification of caseou tuberculous hilar glands.

Functional disorders of the movements of the diaphragms are common in asthma and are readily demonstrated on the screen, as indeed is the improvemen which follows a course of breathing exercises in th physiotherapy department.

Obesity of the patient makes screening more difficult and is one reason for many "unnecessary" films In doubtful cases, confidence in the normality of th upper fields can be reached by increasing the milliamperage to 7 or 8 for a few seconds; but subcutaneou fat can easily be mistaken for a small pleural effusio obliterating the costophrenic angles.

We do not propose to discuss the fluoroscopic examination of the heart shadow; but in all cases it should b inspected in the "straight" view, and also with th patient stationary for a second or two in each obliqu position. An enlarged left auricle or an extended aorta —to mention only two conditions which are easil noted—is often a valuable clue to diagnosis.

ECONOMICS

More and more people are now aware that chest diseas can often be diagnosed radiologically. This partl accounts for the tremendous increase in the number o patients referred to chest clinics. Chest physician spend more and more time sorting healthy wheat from unhealthy chaff, and much public money is squandered on X-ray films because the physician knows that many "silent" lesions will not be found without radiography The present cost of a screening apparatus is no more than the cost of about 400 films for such examinations at a guinea each. Widespread installation of such equipment would save many films and help to relieve congestion in the greatly overworked X-ray departments of our hospitals. This would save not only money but also the chest physicians' time.

OPPOSITE ACTIONS OF THYROID AND ADRENAL HORMONES IN ALLERGIC HYPERSENSITIVITY

D. A. Long
M.D. Lond.

A. A. Miles
M.A. Camb., F.R.C.P.

From the National Institute for Medical Research, London

Among the explanations of the characteristic tissue reactions in rheumatoid arthritis, that of a chronic allergic hypersensitivity has received a good deal of attention (see, for example, Urbach and Gottlieb 1946). The striking modification of these reactions by the administration of adrenocorticotropic hormone (A.C.T.H.) or 'Cortisone' (Hench et al. 1949) is consistent with this explanation, because the reactions of animals artificially hypersensitised to injection of the exciting allergen have also been modified substantially by increase or decrease of the adrenal hormones. Thus, adrenalectomy in guineapigs (Kepinov 1922a) and rats (Flashman 1926) increases sensitivity to anaphylactic shock, whereas adrenocortical extracts temporarily diminish it in guineapigs (Wolfram and Zwemer 1935) and dogs (Dragstedt et al. 1937). Moreover, A.C.T.H. diminishes sensitivity in a variety of established allergic diseases (Bordley et al. 1949).

This enhancement of hypersensitivity by deprivation, and its decrease by the giving, of adrenocortical hormones is matched, in the opposite sense, by the effect of thyroid secretions. Both tuberculin and anaphylactic hypersensitivity are recorded as decreased in thyroidectomised animals by Kepinov (1922b) and Kepinov and Metalnikov (1922); and according to Eickhoff (1939), neither allergic nor anaphylactic hypersensitivity can be induced in thyroidectomised guineapigs, but both develop in these animals when thyroid is given.

EARLIER WORK

The idea of a balanced opposition between thyroid and adrenocortical hormones in the normal animal is of course not new. As early as 1917, Herring demonstrated, in experimental hyperthyroidism, compensatory hypertrophy—and presumably hyperactivity—of the adrenal cortex, and many subsequent observers have confirmed this effect (e.g., Squier and Grabfield 1922, Gohar 1933, Gerlei 1938). In rats, atrophy of the adrenal cortex follows suppression of thyroid activity by thiouracil (Marine and Baumann 1945, see also Zarrow and Money 1949).

Among the further evidence of a thyroid-adrenal balance is the positive nitrogen balance maintained in adrenalectomised dogs by the simultaneous administration of cortin and thyroxine (Koelsche and Kendall 1935); the prolongation of life in adrenalectomised cats by thyroidectomy (Zwemer 1927); the inhibition of increased metabolism in acute experimental thyrotoxicosis by 'Cortidyn' (Oehme 1936); the increased resistance of rats to potassium chloride poisoning induced by cortical extract, and its annulment by thyroid extract (Lowenstein and Zwemer 1943); and the stimulation of thyroid activity and hyperplasia by moderate injury to the adrenal cortex (Scott 1922).

These effects are mainly acute. With prolonged modification of the thyroid secretion, the opposition of the adrenals has other consequences. For example, when Lowenstein and Zwemer gave their rats thyroid for ten days and then rested them for ten days, there was increased resistance to potassium chloride associated with the compensatory hypertrophy of the adrenal cortex. Again, whereas excess of thyroxine for a short period is followed by a drop in the cholesterol content of the adrenals, long-lasting excess induces hypertrophy of the gland and an absolute increase in the cholesterol content (Abelin 1944). Clearly, any antagonism between the two glands must be interpreted in terms of an immediate opposition of available hormones, and of the stimulus one hormone may give to compensatory production or overproduction of the other.

FEATURES OF INVESTIGATION

The relation of the allergic state to the thyroid-adrenal system is still obscure, partly because of the piecemeal evidence, and partly because the adrenal hormones hitherto used in this kind of work have been ill defined. With cortisone available in a purified state, we re-examined this relation in the hope of widening the investigation of problems which up till now have been tackled in terms of the adrenocortical hormones alone. From the preliminary work we record in this paper, three noteworthy features emerge: (1) the opposite nature of thyroxine and cortisone effects in allergy; (2) the swing of allergic reactivity in the opposite direction two weeks after administration of either of the two hormones has ceased; and (3) the use of the tuberculin-sensitive guineapig as a test object for the assay of substances with a cortisone-like effect.

EFFECT OF THYROXINE AND PROPYLTHIOURACIL ON SENSITISATION TO TUBERCULIN

In our first tests with thyroxine (experiment 1), we relied upon twice-weekly intradermal injections of 2000 international units (I.U.) of tuberculin to induce hypersensitivity.

Each injection was made into a different site in the skin of healthy albino guineapigs weighing about 400 g.; and twenty-four hours later the diameter of the reaction to that injection was measured. Three groups of twenty animals were used (fig. 1); those in group I were given 0·2 mg. sodium thyroxine subcutaneously three times a week, and those in group II, 25 mg. propylthiouracil by mouth three times a week; group III was the control. On the 10th day of treatment the tuberculin injections were started.

Sensitivity increased slowly in groups II and III, rapidly in the thyrotoxic animals (group I). On the 28th day, after 18 days' sensitisation, half the animals in groups II and III were given thyroxine; and, while in the remainder hypersensitivity did not increase materially, in these it increased very rapidly. The same increase occurred in ten animals of group I that continued to receive thyroxine; but in ten taken off thyroxine after 28 days, hypersensitivity declined to that of the untreated

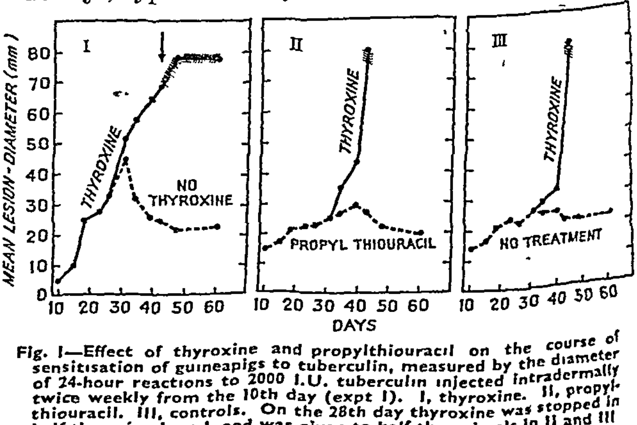

Fig. 1—Effect of thyroxine and propylthiouracil on the course of sensitisation of guineapigs to tuberculin, measured by the diameter of 24-hour reactions to 2000 I.U. tuberculin injected intradermally twice weekly from the 10th day (expt 1). I, thyroxine. II, propylthiouracil. III, controls. On the 28th day thyroxine was stopped in half the animals in I, and was given to half the animals in II and III. Cross-hatching indicates a diffuse erythema of the animal's skin. ↓, death of two animals.

animals in group III. The thyrotoxicosis was not severe; its degree is evident from the variation in body-weight of the animals (fig. 2). It was in fact regulated so as to keep the weights of the animals approximately stationary —that is, if our hypothesis is correct, in a state of approximate balance of thyroid and adrenal hormones. Two animals in group I died after 42 days' thyroxine, with hæmorrhages in the adrenal cortex.

In all the thyroxine-treated animals, the tuberculin reaction at about the 30th day was intense, with a flare-up at the sites of previous tuberculin injections and a diffuse erythema of the skin (see fig. 1).

The hypersensitive reactions of the animals treated with propylthiouracil did not differ materially from those of untreated animals; and in both groups the later treatment with thyroxine had the same effect. According to our other results (see below) we might expect a diminution of hypersensitivity by adrenal hormones becoming dominant as a result of depressed thyroid activity. Possibly the appropriate adjustment of the adrenal-thyroid balance during propylthiouracil treatment is more rapid than that during thyroxine intoxication, though on this we have no direct evidence. But the enhancement of hypersensitivity by thyroxine was indubitable; and it disappeared about 10 days after the thyroxine injections ceased. Thyroxine does not appear to have affected the *rate* of sensitisation, because after 10 days of the drug the animals in groups II and III reacted as violently to tuberculin as those in group I that had had thyroxine during the whole period of sensitisation.

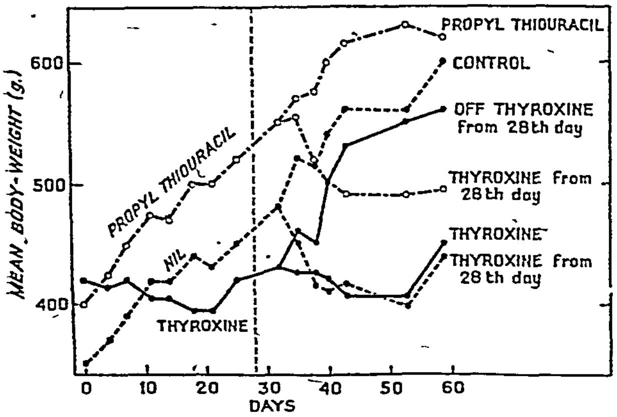

Fig. 2—Mean weights of the guineapigs in expt I. Groups and treatments as in fig. I. Treatment of half the animals in each group changed at the 28th day.

EFFECT OF THYROXINE, A.C.T.H., AND CORTISONE ON HYPERSENSITIVITY OF B.C.G.-INFECTED ANIMALS

B.C.G.-infected Guineapigs as Test Animals.—The rest of our tests were made with B.C.G.-infected guineapigs. Albino guineapigs, weighing 350–400 g., were given 2–5 mg. wet weight of B.C.G. into the right adductor muscles of the thigh and were submitted to tuberculin skin-tests some 30–48 days after this injection. They were housed under standard conditions and given Bruce and Parkes's (1947) pellet diet and unlimited cabbage. We chose the tuberculin-sensitive guineapigs for three reasons:

1. Tuberculin sensitivity exemplifies the so-called "bacterial allergy," as distinct from the "anaphylactic" or "Arthus" hypersensitivity; and we feel that if allergy in fact predominates in clinical syndromes which, like rheumatoid arthritis, yield to treatment with cortisone, it is likely to be "bacterial" in type.

2. The allergy is induced by infection with living B.C.G., and, like natural allergy, is a progressive state, at least during the period in which we made the tests.

3. We had, with these animals, developed a method for measuring changes in allergy with some precision. Measurement of hypersensitivity is notoriously difficult; only very roughly quantitative statements are usually possible. Tuberculosis allergy may be crudely measured by the Mantoux intradermal test, but the end-point thus achieved is relatively coarse. A better measure proved to be possible by the discovery (which we later found had been made by Wadley [1949]) that the diameter of the 24-hour skin lesion produced by a constant volume of tuberculin solution was directly proportional to the logarithm of the concentration of tuberculin. (A similar relation holds for diphtheria toxin [Miles 1949].)

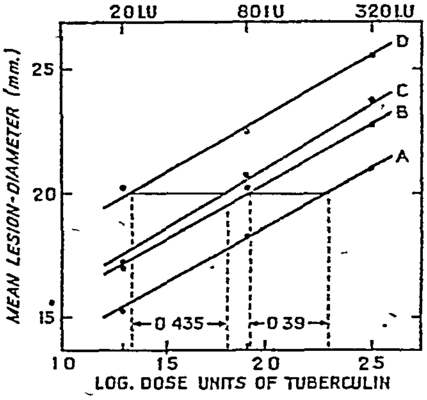

Fig. 3—Dose-responses to 20, 80, and 320 I.U. tuberculin in sensitive guineapigs. A, control; B, treated with thyroxine; C, control 14 days later; D, B 14 days later, having had no thyroxine since test B. (Table II, expt 2.)

Method of Estimating Hypersensitivity.—In fig. 3 the mean lesion-diameters at 24 hours in four groups of infected guineapigs are plotted against the log dose of tuberculin, which was injected in 0·2 ml. volumes in doses of 20, 80, and 320 I.U. into the dorsolateral skin of the depilated animals. For each group the mean responses to the doses fall approximately on a straight line. All our tests were designed to yield data susceptible to the standard methods of regression analysis (Fisher 1947); and by these it was possible to prove that in each comparative test the dose-response lines were substantially straight and parallel to one another, but differed significantly in position. One such analysis is recorded in table I; the probability (P) that differences between responses to the three doses of tuberculin (*b*) and between responses by each group of animals as a whole (*a*), and that the two-dose response lines are not linear (*c*), is in all cases less than 1 in 100.

In fig. 3, parallel regression-lines are fitted to A and B, and to C and D, which represent pairs of tests on thyroxine-treated animals (table II, expt 2). Thus the horizontal distance between A and B is 0·39, which is the log ratio of the doses of tuberculin required to elicit a lesion of given diameter in the guineapigs of the two groups. That is, group B animals require antilog 0·39=2·5 times as little tuberculin as group A animals to give a reaction of, say, 20 mm. diameter, and are therefore 2·5 times more hypersensitive. Similarly group C is antilog 0 435=2·7 times less sensitive than group D.

This method permits a precise numerical estimate of hypersensitivity and will, we hope, prove useful in the investigation both of allergy and of substances that modify allergy. The linear relation of log-dose with

TABLE I—ANALYSIS OF VARIANCE: DATA FROM THE EXPERIMENT RECORDED IN FIG. 3, A AND B

Variance	DF	Mean square	F	P

OPPOSITE ACTIONS OF THYROID AND ADRENAL HORMONES IN ALLERGIC HYPERSENSITIVITY

D. A. Long
M.D. Lond.

A. A. Miles
M.A. Camb., F.R.C.P.

From the National Institute for Medical Research, London

Among the explanations of the characteristic tissue reactions in rheumatoid arthritis, that of a chronic allergic hypersensitivity has received a good deal of attention (see, for example, Urbach and Gottlieb 1946). The striking modification of these reactions by the administration of adrenocorticotropic hormone (A.C.T.H.) or 'Cortisone' (Hench et al. 1949) is consistent with this explanation, because the reactions of animals artificially hypersensitised to injection of the exciting allergen have also been modified substantially by increase or decrease of the adrenal hormones. Thus, adrenalectomy in guineapigs (Kepinov 1922a) and rats (Flashman 1926) increases sensitivity to anaphylactic shock, whereas adrenocortical extracts temporarily diminish it in guineapigs (Wolfram and Zwemer 1935) and dogs (Dragstedt et al. 1937). Moreover, A.C.T.H. diminishes sensitivity in a variety of established allergic diseases (Bordley et al. 1949).

This enhancement of hypersensitivity by deprivation, and its decrease by the giving, of adrenocortical hormones is matched, in the opposite sense, by the effect of thyroid secretions. Both tuberculin and anaphylactic hypersensitivity are recorded as decreased in thyroidectomised animals by Kepinov (1922b) and Kepinov and Metalnikov (1922); and according to Eickhoff (1939), neither allergic nor anaphylactic hypersensitivity can be induced in thyroidectomised guineapigs, but both develop in these animals when thyroid is given.

EARLIER WORK

The idea of a balanced opposition between thyroid and adrenocortical hormones in the normal animal is of course not new. As early as 1917, Herring demonstrated, in experimental hyperthyroidism, compensatory hypertrophy—and presumably hyperactivity—of the adrenal cortex, and many subsequent observers have confirmed this effect (e.g., Squier and Grabfield 1922, Gohar 1933, Gerlei 1938). In rats, atrophy of the adrenal cortex follows suppression of thyroid activity by thiouracil (Marine and Baumann 1945, see also Zarrow and Money 1949).

Among the further evidence of a thyroid-adrenal balance is the positive nitrogen balance maintained in adrenalectomised dogs by the simultaneous administration of cortin and thyroxine (Koelsche and Kendall 1935); the prolongation of life in adrenalectomised cats by thyroidectomy (Zwemer 1927); the inhibition of increased metabolism in acute experimental thyrotoxicosis by 'Cortidyn' (Oehme 1936); the increased resistance of rats to potassium chloride poisoning induced by cortical extract, and its annulment by thyroid extract (Lowenstein and Zwemer 1943); and the stimulation of thyroid activity and hyperplasia by moderate injury to the adrenal cortex (Scott 1922).

These effects are mainly acute. With prolonged modification of the thyroid secretion, the opposition of the adrenals has other consequences. For example, when Lowenstein and Zwemer gave their rats thyroid for ten days and then rested them for ten days, there was increased resistance to potassium chloride associated with the compensatory hypertrophy of the adrenal cortex. Again, whereas excess of thyroxine for a short period is followed by a drop in the cholesterol content of the adrenals, long-lasting excess induces hypertrophy of the gland and an absolute increase in the cholesterol content (Abelin 1944). Clearly, any antagonism between the two glands must be interpreted in terms of an immediate opposition of available hormones, and of the stimulus one hormone may give to compensatory production or overproduction of the other.

FEATURES OF INVESTIGATION

The relation of the allergic state to the thyroid-adrenal system is still obscure, partly because of the piecemeal evidence, and partly because the adrenal hormones hitherto used in this kind of work have been ill defined. With cortisone available in a purified state, we re-examined this relation in the hope of widening the investigation of problems which up till now have been tackled in terms of the adrenocortical hormones alone. From the preliminary work we record in this paper, three noteworthy features emerge: (1) the opposite nature of thyroxine and cortisone effects in allergy; (2) the swing of allergic reactivity in the opposite direction two weeks after administration of either of the two hormones has ceased; and (3) the use of the tuberculin-sensitive guineapig as a test object for the assay of substances with a cortisone-like effect.

EFFECT OF THYROXINE AND PROPYLTHIOURACIL ON SENSITISATION TO TUBERCULIN

In our first tests with thyroxine (experiment 1), we relied upon twice-weekly intradermal injections of 2000 international units (I.U.) of tuberculin to induce hypersensitivity.

Each injection was made into a different site in the skin of healthy albino guineapigs weighing about 400 g.; and twenty-four hours later the diameter of the reaction to that injection was measured. Three groups of twenty animals were used (fig. 1); those in group I were given 0.2 mg. sodium thyroxine subcutaneously three times a week, and those in group II, 25 mg. propylthiouracil by mouth three times a week; group III was the control. On the 10th day of treatment the tuberculin injections were started.

Sensitivity increased slowly in groups II and III, rapidly in the thyrotoxic animals (group I). On the 28th day, after 18 days' sensitisation, half the animals in groups II and III were given thyroxine; and, while in the remainder hypersensitivity did not increase materially, in these it increased very rapidly. The same increase occurred in ten animals of group I that continued to receive thyroxine; but in ten taken off thyroxine after 28 days, hypersensitivity declined to that of the untreated

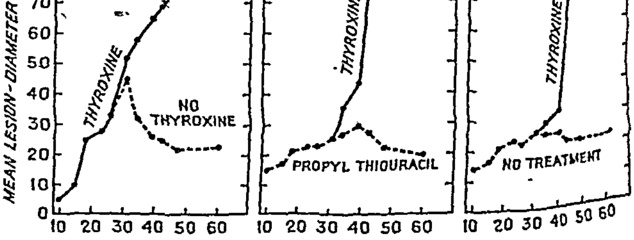

Fig. 1—Effect of thyroxine and propylthiouracil on the course of sensitisation of guineapigs to tuberculin, measured by the diameter of 24-hour reactions to 2000 I.U. tuberculin injected intradermally twice weekly from the 10th day (expt I). I, thyroxine. II, propylthiouracil. III, controls. On the 28th day thyroxine was stopped in half the animals in I, and was given to half the animals in II and III. Cross-hatching indicates a diffuse erythema of the animal's skin. ↓, death of two animals.

animals in group III. The thyrotoxicosis was not severe; its degree is evident from the variation in body-weight of the animals (fig. 2). It was in fact regulated so as to keep the weights of the animals approximately stationary—that is, if our hypothesis is correct, in a state of approximate balance of thyroid and adrenal hormones. Two animals in group I died after 42 days' thyroxine, with hæmorrhages in the adrenal cortex.

In all the thyroxine-treated animals, the tuberculin reaction at about the 30th day was intense, with a flare-up at the sites of previous tuberculin injections and a diffuse erythema of the skin (see fig. 1).

The hypersensitive reactions of the animals treated with propylthiouracil did not differ materially from those of untreated animals; and in both groups the later treatment with thyroxine had the same effect. According to our other results (see below) we might expect a diminution of hypersensitivity by adrenal hormones becoming dominant as a result of depressed thyroid activity. Possibly the appropriate adjustment of the adrenal-thyroid balance during propylthiouracil treatment is more rapid than that during thyroxine intoxication, though on this we have no direct evidence. But the enhancement of hypersensitivity by thyroxine was indubitable; and it disappeared about 10 days after the thyroxine injections ceased. Thyroxine does not appear to have affected the *rate* of sensitisation, because after 10 days of the drug the animals in groups II and III reacted as violently to tuberculin as those in group I that had had thyroxine during the whole period of sensitisation.

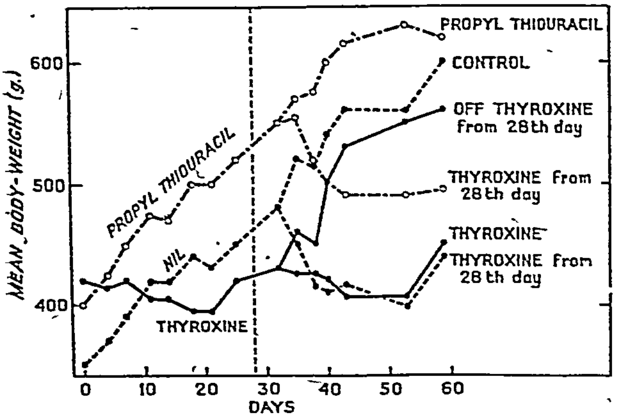

Fig. 2—Mean weights of the guineapigs in expt I. Groups and treatments as in fig. I. Treatment of half the animals in each group changed at the 28th day.

EFFECT OF THYROXINE, A.C.T.H., AND CORTISONE ON HYPERSENSITIVITY OF B.C.G.-INFECTED ANIMALS

B.C.G.-infected Guineapigs as Test Animals.—The rest of our tests were made with B.C.G.-infected guineapigs. Albino guineapigs, weighing 350–400 g., were given 2–5 mg. wet weight of B.C.G. into the right adductor muscles of the thigh and were submitted to tuberculin skin-tests some 30–48 days after this injection. They were housed under standard conditions and given Bruce and Parkes's (1947) pellet diet and unlimited cabbage. We chose the tuberculin-sensitive guineapigs for three reasons:

1. Tuberculin sensitivity exemplifies the so-called "bacterial allergy," as distinct from the "anaphylactic" or "Arthus" hypersensitivity; and we feel that if allergy in fact predominates in clinical syndromes which, like rheumatoid arthritis, yield to treatment with cortisone, it is likely to be "bacterial" in type.

2. The allergy is induced by infection with living B.C.G., and, like natural allergy, is a progressive state, at least during the period in which we made the tests.

3. We had, with these animals, developed a method for measuring changes in allergy with some precision. Measurement of hypersensitivity is notoriously difficult; only very roughly quantitative statements are usually possible. Tuberculosis allergy may be crudely measured by the Mantoux intradermal test, but the end-point thus achieved is relatively coarse. A better measure proved to be possible by the discovery (which we later found had been made by Wadley [1949]) that the diameter of the 24-hour skin lesion produced by a constant volume of tuberculin solution was directly proportional to the logarithm of the concentration of tuberculin. (A similar relation holds for diphtheria toxin [Miles 1949].)

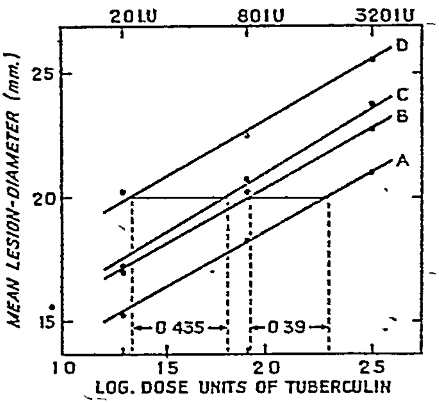

Fig. 3—Dose-responses to 20, 80, and 320 I.U. tuberculin in sensitive guineapigs. A, control; B, treated with thyroxine; C, control 14 days later; D, B 14 days later, having had no thyroxine since test B. (Table II, expt 2.)

Method of Estimating Hypersensitivity.—In fig. 3 the mean lesion-diameters at 24 hours in four groups of infected guineapigs are plotted against the log dose of tuberculin, which was injected in 0·2 ml. volumes in doses of 20, 80, and 320 I.U. into the dorsolateral skin of the depilated animals. For each group the mean responses to the doses fall approximately on a straight line. All our tests were designed to yield data susceptible to the standard methods of regression analysis (Fisher 1947); and by these it was possible to prove that in each comparative test the dose-response lines were substantially straight and parallel to one another, but differed significantly in position. One such analysis is recorded in table I: the probability (P) that differences between responses to the three doses of tuberculin (*b*) and between responses by each group of animals as a whole (*a*), and that the two-dose response lines are not linear (*c*), is in all cases less than 1 in 100.

In fig. 3, parallel regression-lines are fitted to A and B, and to C and D, which represent pairs of tests on thyroxine-treated animals (table II, expt 2). Thus the horizontal distance between A and B is 0·39, which is the log ratio of the doses of tuberculin required to elicit a lesion of given diameter in the guineapigs of the two groups. That is, group B animals require antilog 0·39=2·5 times as little tuberculin as group A animals to give a reaction of, say, 20 mm. diameter, and are therefore 2·5 times more hypersensitive. Similarly group C is antilog 0·435=2·7 times less sensitive than group D.

This method permits a precise numerical estimate of hypersensitivity and will, we hope, prove useful in the investigation both of allergy and of substances that modify allergy. The linear relation of log-dose with

TABLE II—SYNOPSIS OF HYPERSENSITIVITY ESTIMATIONS IN B.C.G.-INFECTED GUINEAPIGS

Expt no.	No. of guinea-pigs	Treatment	Hypersensitivity tests			
			Day	Ratio	Day	Ratio
2	16	35th–47th day, thyroxine	47th	2 5	61st	1·0
	24	Nil		1 0		2·7
3	10	30th day, A.C.T.H.	30th 2½ hr. later	1·0	44th	3·4
	10	Nil		3 6		1·0
4	6	46th–48th day, cortisone	48th 4 hr. later	1 0	62nd	9·0
	6	Nil		4 0		1 0

Days refer to duration of B.C.G. infection. Doses: thyroxine 0 2 mg. thrice weekly; A.C.T.H. 0 6 mg., cortisone 1 mg. daily, all subcutaneously.

lesion-diameter holds good for a number of substances besides diphtheria toxin and tuberculin; we have in this laboratory demonstrated its validity for scarlet-fever toxin, *Clostridium welchii* α-toxin, histamine, and some histamine-liberating substances.

Results.—Table II summarises three experiments. The small number of animals in experiments 3 and 4 was dictated by the need for economy in A.C.T.H. and cortisone. However, the response of the guineapigs in each group was surprisingly consistent; and even with the few animals used, analysis showed clearly that the ratio of hypersensitivities was statistically significant ($P = 0{\cdot}05$).

The A.C.T.H. was a peptide prepared by Dr. C. J. O. R. Morris, in whose test-rats 1 μg. produced an approximately 30% decrease in adrenal ascorbic acid. The cortisone was part of a batch sent to Sir Henry Dale at the National Institute for Medical Research by E. C. Kendall in 1942.

In experiment 2, 12 days' treatment with thyroxine increased hypersensitivity 2 5-fold, compared with controls. After a further 14 days, during which no more thyroxine was given, hypersensitivity declined until it was only 1:2 7 that of the controls.

In experiment 3 a single subcutaneous dose of A.C.T.H. decreased hypersensitivity 3·6-fold. Two and a half hours was chosen as the interval between A.C.T.H. and the tuberculin injection, because after this interval the effect of A.C.T.H. on adrenal ascorbic acid and cholesterol, and, according to Sayers et al. (1944), on the output of cortical hormone, begins to mature.

In experiment 4 three daily subcutaneous doses of 1 mg. cortisone decreased hypersensitivity fourfold, when tuberculin was given 4 hours after the last injection.

In experiments 3 and 4 the effect was later reversed. Fourteen days after a single dose of A.C.T.H. the animals were 3·4 times as sensitive as the controls; and fourteen days after three doses of cortisone hypersensitivity was nearly 9 times that in the controls.

DISCUSSION

The most striking results are: (1) the opposite effect of thyroxine on the one hand, and of cortisone and A.C.T.H. on the other; and (2) diminution of the effect some days after the administration of the hormone has ceased, and furthermore a swing in the opposite direction. With cortisone at least, this parallels the exacerbation of symptoms in patients with rheumatoid arthritis when the drug is withdrawn (Hench et al. 1949).

The overswing can be explained in terms of the opposition of thyroid and adrenal cortex. Such an explanation must be largely speculative; but, quite apart from their opposite effects on hypersensitivity when tested in *different* groups of animals, we have some evidence that the thyroid and adrenocortical hormones opposed each other in the same animal. Thus animals given thyroxine throughout experiment 1 had enlarged adrenals, with pronounced cortical hypertrophy. Fig. 4 shows the maximum transverse sections of the adrenals from these animals, compared with those from the control group. The extreme sizes in the picture are the biggest and smallest found in each group, and the inner four sections represent intermediate sizes, which in each group were evenly distributed between the extremes. There was evidently compensatory hypertrophy of the adrenal cortex, and histologically the thyroids were in the resting stage. In experiment 2, therefore, it is not unreasonable to postulate an excessive adrenocortical activity for some days after the end of thyroxine injections.

With regard to the overswing in the other direction, after stimulation of the cortex by A.C.T.H. or after an excessive dose of cortisone, an overcompensatory response of the thyroid, becoming manifest in its effect on allergy two weeks later, is clearly possible.

Direct evidence of the opposition of the two glands, the nature of the adrenocortical hormones immediately or mediately responsible for modification of the allergic

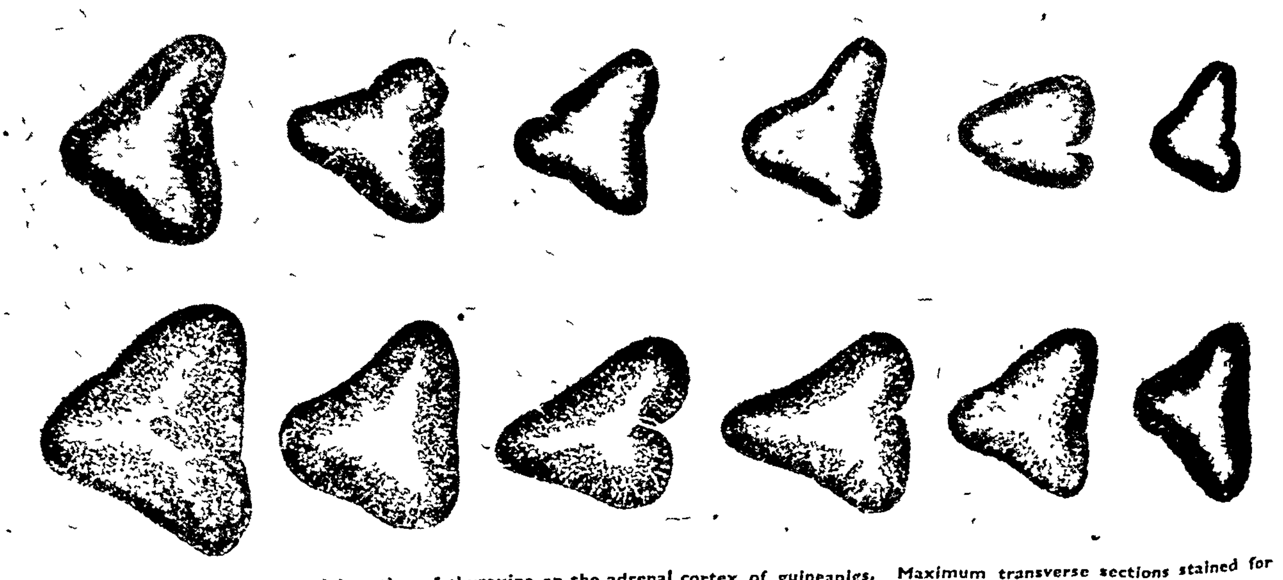

Fig. 4—Effect of prolonged administration of thyroxine on the adrenal cortex of guineapigs. Maximum transverse sections stained for cholesterol. Above: controls. Below: thyroxine.

effects, and the time relations of the "overswing" in sensitivity remain to be demonstrated. Nevertheless, we feel there is a strong a priori case for extending the investigation of adrenocortical effects on pathological processes to include the thyroid gland. It is unlikely that these effects can be described completely in terms of an adrenal-thyroid system, but the thyroid may prove to have a greater direct influence than has hitherto been suspected.

Finally, it is evident from our results with animals infected with B.C.G. (a microbe of low virulence for the guineapig) that a pathological state developing as a result of the infection can be definitely, readily, and reversibly modified by simple changes in the balance of hormones. In rheumatoid arthritis Hench and his colleagues find it "increasingly difficult to harmonize the microbic theory of the origin of rheumatoid arthritis with the phenomenon of relief by jaundice or pregnancy." Though we would support any attempt to eliminate all unnecessary hypotheses about rheumatoid arthritis, we feel, as a result of our investigations, that there is nothing contradictory in the hypothesis of certain consequences of infection (some of them perhaps allergic in nature) being modified in pregnancy or jaundice by accompanying biochemical changes—some of them perhaps hormonal in origin.

SUMMARY

Past experimental work on the relation of the thyroid and adrenal cortex suggests that their hormones are opposed to each other. Allergic and anaphylactic hypersensitivity are among the physiological and pathological processes influenced in this way. Thyroxine appears to increase, and the adrenocortical hormones to decrease, hypersensitivity.

Using hypersensitivity to tuberculin in guineapigs as an example of "bacterial" allergy, we devised a quantitative measure of allergy and have shown that:

1. Moderate thyrotoxicosis of two weeks' duration increases hypersensitivity, whereas either three daily injections of cortisone or one injection of A.C.T.H. diminishes it; moderate doses of propylthiouracil did not affect it.

2. Fourteen days after stopping the thyroxine injections there was a swing of the thyroxine effect in the opposite direction, and the animals were *less* hypersensitive than the controls.

3. Fourteen days after the treatment with either cortisone or A.C.T.H., there was also a swing in the opposite direction, the animals now being *more* hypersensitive than the controls.

In the thyroxine-treated animals there was adrenocortical hypertrophy, which may account for the "overswing" in allergy after fourteen days without thyroxine. The "overswing" in the A.C.T.H. and cortisone-treated animals may be due to an analogous overcompensation in thyroid activity.

We are indebted to Mr. C. J. O. R. Morris, PH.D., for the A.C.T.H., to Mrs. R. Pitt-Rivers for the thyroxine used, to Dr. Knud Tolderlund, of the State Serum Institute, Copenhagen, for the B.C.G., and to Dr. W. L. M. Perry for the statistical analyses.

PROCAINE PENICILLIN WITH ALUMINIUM MONOSTEARATE

EFFECTS OF A SINGLE LARGE DOSE IN BED AND AMBULANT PATIENTS

OF the slow-release penicillin preparations recently introduced procaine penicillin in oil with 2% aluminium monostearate has proved the most effective in delaying absorption of the injected penicillin. Since its introduction by Buckwalter and Dickison (1948) several workers have compared its properties with those of soluble penicillin in oil or wax and procaine penicillin in oil or water (Robinson et al. 1948, Thomas et al. 1948, Floyd 1949, Young et al. 1949). Most of the work reported so far has been aimed at obtaining therapeutic blood-penicillin levels lasting for 24–48 hours; and it is clear that a single intramuscular injection of 300,000 units of the aluminium-stearate preparation will achieve this object.

Kitchen et al. (1949) showed that larger doses (1,200,000 and 2,400,000 units) maintained a blood-penicillin level of 0·03 unit per ml., on the average, for about 7 days. Young et al. (1949) found that in eight of their patients a dose of 2,000,000 units gave continuous therapeutic blood-penicillin levels for 6–8 days. Neither of these groups of workers states whether their patients were confined to bed. A single-injection method which consistently gives a therapeutic effect of this duration would be particularly useful in treating outpatients with minor infective conditions since it would considerably reduce the number of injections given in the outpatient department, with obvious advantages for patients, nurses, and doctors.

We have investigated the duration of therapeutic blood-penicillin levels in two main groups of patients after a single intramuscular injection of 2,000,000 units of procaine penicillin with aluminium stearate in arachis oil. It was realised that results in bed patients and ambulant patients might be different. Boger et al. (1948) and Emery et al. (1949) noted that after the injection of procaine penicillin (without aluminium stearate) the blood-penicillin levels tended to fall more rapidly in ambulant patients than in bed patients. For this reason we have compared results in these two groups. Among those included in the trial were 48 outpatients with boils, carbuncles, and minor sepsis of the hand, and in these the clinical results were noted. A statistical comparison of these cases with others treated in other ways was not, however, attempted. Among the surgical bed patients were five with severe bronchitis and emphysema. It was hoped that penicillin given in this way, at the time of operation, might prevent the postoperative chest complications likely to occur in such cases. Patients thought to have defective renal function were excluded from the investigation.

METHODS

The procaine penicillin with aluminium stearate was supplied by Allen & Hanburys Ltd. The injections were given into the upper outer quadrant of the buttock, the whole dose of 2,000,000 units (6·6 ml.) being given into the one buttock. The bed patients had no pain after the injection, but ambulant patients varied in their reactions. Most complained of a minor degree of stiffness developing about 6 hours later and lasting 12–24 hours, but a few had more severe aching pain and stiffness lasting up to 3 days. Probably these reactions may be minimised by making sure that the injection is given deep into the muscle.

The material was withdrawn from the ampoule with a French's serum needle. The injections were given through a no. 1 intramuscular needle. Though the withdrawal was reasonably easy, considerable force had to be used for the injection. This disadvantage was overcome by the use of a metal holder into which the syringe was clipped (fig. 1), the dose being injected by the turning of a screw thread. The introduction of this simple device (constructed by the hospital instrument technician) made the giving of the injections quite easy and in consequence more popular with the nurses. Less viscid preparations, which, it is understood, are now obtainable, may be still simpler to administer and will render this apparatus unnecessary.

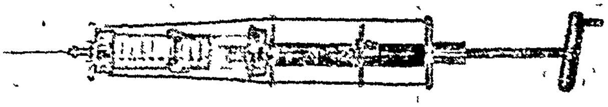

Fig. 1—Screw adapter for syringe.

Serum-penicillin levels were estimated by a modification (Gillespie and Alder 1948) of the method of Fleming and Smith (1947), standard penicillin solutions in normal serum being put up in duplicate with each batch of tests. A staphylococcus was used as the test organism. On some occasions parallel tests were put up with a hæmolytic streptococcus, with similar results. A serum-penicillin concentration of 0 06 unit per ml. was regarded as the minimal therapeutic level.

RESULTS

Bed Patients

These consisted of twenty-four surgical and eleven medical cases. It was intended to follow each patient's serum-penicillin level until it fell below the therapeutic minimum, but discharge from hospital made this impossible in ten surgical and four medical patients. However, all the cases were followed for at least 7 days, and most for a longer period.

In the surgical cases the serum-penicillin level was estimated daily, with some omissions, usually at week-ends. All these patients had operations (from simple appendicectomy to extensive thoracotomy with œsophageal resection) a day or two before or after the injection. Their ages ranged from 19 to 72 years (average 48). The results are summarised in the accompanying table, and the average effects shown in fig. 2. The daily serum-penicillin levels varied considerably from case to case. Those on the 1st day after injection ranged from 0·25 to 2·0 units per ml. Thereafter they gradually fell, sometimes with fluctuations, but, in all but two cases, stayed above the therapeutic minimum for 7–12 days. Of the two exceptions, one maintained a therapeutic level for 5 days, and in the other the duration was not exactly determined.

SERUM-PENICILLIN LEVELS IN DIFFERENT CLASSES OF PATIENTS AND IN AMBULANT VOLUNTEERS

Category	No. tested	Days after injection	Serum-penicillin level (units/ml.)	
			≧0·06	<0 06
Bed patients, surgical	19	9	13	6
Bed patients, medical	9	”	2	7
Bed patients, surgical	24	7	22	2
Bed patients, medical	11	”	9	2
Ambulant patients ..	28	”	7	21
Ambulant volunteers	13	”	2	9
Ambulant patients (a further series) ..	20	5	15	5
Ambulant volunteers	13	”	9	4
Ambulant volunteers	13	3	13	0

The eleven medical bed patients were aged from 11 to 73 years (average 45). None was acutely ill. Serum-penicillin levels were estimated on the 1st, 5th, or 6th and subsequent days after injection (see table and fig. 2). The levels on the 1st day ranged from 0·12 to 2 0 units per ml., and then stayed above the therapeutic minimum for 7–12 days in all but two cases. In one of these the effect lasted for 6 days; in the other the duration was not exactly determined. In general the duration of the therapeutic levels was less than in the surgical patients, as shown by the results on the 9th day (see table).

It is therefore evident that our results in medical and surgical bed patients agree with those of Young et al. (1949).

Ambulant Patients and Volunteers

In twenty-eight ambulant outpatients (with boils, carbuncles, and minor sepsis of the hand) the serum-penicillin level was estimated on the 7th day after injection. These patients were aged 22–70 (average 37). When it was found that twenty-one of the patients did not maintain their blood-penicillin levels for this period, a further series of twenty similar cases, aged 15–49 (average 31), was tested 5 days after the injection (see table).

In addition, an attempt was made to establish more exactly the duration of the therapeutic levels in ambulant cases by estimating the serum-penicillin levels daily in thirteen ambulant healthy volunteers, who were medical students aged 20–30. On the 1st day after injection their blood-penicillin levels ranged from 0·06 to 1·0 unit per ml., but they fell more rapidly than in the bed patients (see table and fig. 2); twelve of the thirteen volunteers maintained their therapeutic levels for 4 days, nine for 5 days, two for 7 days, and none for a longer period.

Influence of Age and Surgical Operations

Excretion of penicillin may be slower in elderly people than in the young. Since the bed patients were on the whole older than the ambulant patients and volunteers, it was important to see if age played a significant part

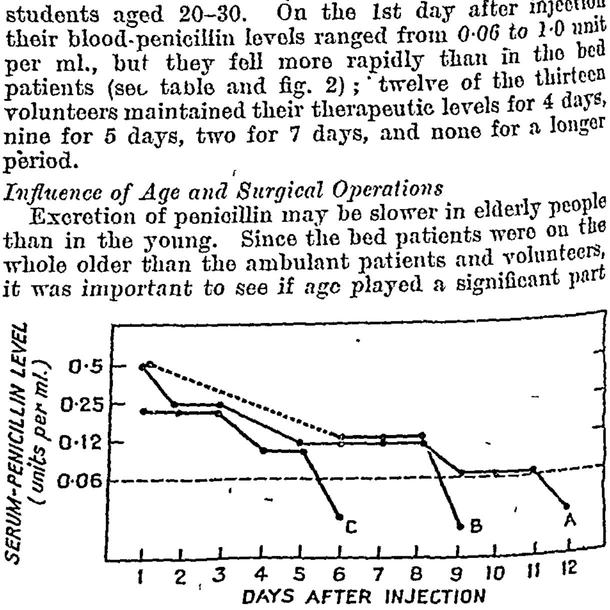

Fig. 2—Median serum-penicillin levels in: A, surgical bed patients; B, medical bed patients; C, ambulant volunteers. Broken line: minimal therapeutic level.

in producing the striking difference between the two groups. Of the thirty-five bed patients sixteen were under the age of 50 (average 34), and in them the average duration of the therapeutic serum-penicillin level was more than 8 days. The average duration in the five bed patients under the age of 30 was more than 9 days. These figures do not exclude some effect due to age, but do show that age by itself was not responsible for the striking differences found between bed and ambulant patients. Similarly it is apparent from our results that operations have not caused the striking differences between the bed and ambulant cases. Nevertheless, possibly because of their relative immobility, the surgical bed patients on the whole maintained their serum-penicillin levels longer than the medical bed patients.

Clinical Results

The clinical effectiveness of this method of giving penicillin can be finally assessed only by an adequate statistical comparison with similar cases treated by other methods. No such comparison has been attempted in this investigation. All that can be said is that the clinical results obtained in forty-eight outpatients with minor septic conditions have been similar to what one would have expected from courses of soluble penicillin injections. The results were also promising in five elderly bed patients with severe bronchitis and emphysema, who remained free from chest complications after major surgical operations.

Complications

No case of sensitivity to penicillin or the other constituents of the preparation was observed in this series, but one patient developed a localised fibrous mass in the buttock. This was thought to be due to the fact that the injection had not been made deep into the substance of the muscle and some had leaked into the subcutaneous tissue. Another patient developed an abscess (coliform bacillus) which discharged itself on the 8th day.

DISCUSSION

The striking difference in the duration of therapeutic blood-penicillin levels between bed patients and ambulant patients is probably a result of the much greater activity and blood-supply of the gluteal muscles in the ambulant patients. This difference must be borne in mind if the single-large-injection method is used.

The arguments in favour of maintaining a steady blood-penicillin level, rather than the discontinuous administration of large doses, have been reviewed by Wayne et al. (1949), who conclude that the evidence, so far as it goes, is in favour of the former. However, the relation between blood-penicillin levels and therapeutic effectiveness is still partly speculative. Further work may show that different types of infection respond best to different methods of administration.

The single-large-injection method should be a convenient way of giving prophylactic penicillin cover for surgical operations in patients who are likely to develop infective complications—e.g., dental extractions in cases of endocarditis and major operations (especially emergency operations) on patients with upper or lower respiratory infections.

SUMMARY

Single injections of 2,000,000 units (6·6 ml.) of procaine penicillin with aluminium stearate were given to thirty-five bed patients (twenty-four surgical and eleven medical) and to forty-eight ambulant patients and thirteen healthy ambulant volunteers. The durations of bacteriostatic blood-penicillin levels were compared in the bed and ambulant groups.

Almost all the bed patients maintained their blood-penicillin levels for at least 6 or 7 days, and most for a longer period. In the ambulant persons the effect was distinctly shorter: it lasted for 5 days in about two-thirds of those tested, but in most cases it had disappeared by the 7th day.

The difference is thought to be largely due to the better blood-supply to the gluteal muscles produced by activity.

The clinical results were satisfactory in forty-eight outpatients with minor septic conditions, but the value of the method cannot be fully assessed without controlled clinical trials.

Single large injections will be useful prophylactically in providing penicillin cover for operations.

Our thanks are due to Prof. R. Milnes Walker for his advice and encouragement, Mr. A. E. Christmas for making the syringe holders, and Miss Nora Glen and Mr. V. G. Alder for invaluable technical assistance.

Medical Societies

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY

Breech Delivery

AT a meeting of this society on Feb. 24, under the presidency of Mr. H. HARVEY EVERS, fœtal mortality associated with breech delivery was discussed by Mr. L. W. COX.

Analysing the results of breech deliveries at the Liverpool Maternity Hospital between 1933 and 1949, Mr. Cox pointed out that refinements in technique had brought about a consistent improvement; during the last five years, of 374 infants only 12 were lost—a mortality of 3·2%. The mortality was high in the child weighing under 5 lb. or over 9 lb. Mr. Cox observed that in hospital practice the mortality in multigravidæ tended to be high, because in many centres only unfavourable cases of breech presentation in the multigravida were referred for hospital confinement.

Intracranial injury was still the most important cause of fœtal death. The Liverpool Maternity Hospital figures showed that in breech cases delivery at home increased the risk. All breech deliveries should be conducted in hospital.

Whether external version should be carried out was a question to be left to the individual operator.

Mr. C. M. MARSHALL pointed out that the essentials of the Burns-Marshall method of delivering the aftercoming head were that the child should be allowed to hang, and that traction should then be applied to its legs and trunk lifted upwards towards the mother. How long the child should be allowed to remain had never been decided by either of the inventors of the method; but Mr. Marshall allowed the child to remain pendant only for a very short time—usually long enough to allow him to rinse his hands in solution.

The PRESIDENT strongly advocated presacral block. In a discussion of Løvset's manœuvre some members suggested that it was one of the greatest advances in the technique of breech delivery, while other maintained that it was nothing more than a debased version of the method described many years ago by Potter.

Reviews of Books

The Common Infectious Diseases

H. STANLEY BANKS M.A., M.D. Glasg., F.R.C.P., D.P.H., physician-superintendent, Park Hospital, London. London: Edward Arnold. 1949. Pp. 354. 21*s.*

THIS concisely written and well-illustrated handbook is based on Dr. Banks's practice and teaching. It is intended for students and postgraduates—particularly, perhaps, general practitioners attending clinical courses on fevers. Some of the views and methods are debatable: not all will favour routine chemoprophylaxis with small doses of sulphonamides in measles wards, for example. As might be expected, the chapter on meningococcal fever is comprehensive, but there are also sound accounts of the other common fevers—though paratyphoid receives rather scant measure. The last chapter, on infective gastro-enteritis of infants, is among the best. Dr. Banks stresses the formidable nature of this disorder in children's hospitals and nurseries and the importance of early segregation in individual cells with complete barrier-nursing. Modern treatment of this major disease, and—equally important—its nursing and general management, are clearly described. To the opening chapter on diphtheria Dr. L. J. M. Laurent has contributed an appendix on the electrocardiogram.

Some of the claims to "priority" made in the preface are a little surprising. "Priorities," like snap, is a game for any number of players, and except that prefaces to first editions are commonly repeated in later ones—which in this case are certain to be called for—the subject is perhaps not worth discussing, especially in a rapidly developing branch of medicine where values change so rapidly. But surely the real pioneers of the "intensive" intravenous antitoxin treatment of diphtheria were W. H. Park of New York, who urged the intravenous route in 1913, and V. Bie of Copenhagen, who at the Blegdams Hospital injected "massive" doses, in part intravenously, from 1920 onwards. However, the disputable preface does not detract from the very real value of the book.

Recent Advances in Social Medicine

By ALAN CARRUTH STEVENSON, B.SC., M.D., M.R.C.P., D.P.H., professor of social and preventive medicine, Queen's University, Belfast. London: J. & A. Churchill. 1950. Pp. 241. 18*s.*

Professor Stevenson has not attempted, in less than 250 pages, to cover the whole of social medicine, but has chosen a group of subjects significant for undergraduate and postgraduate students of preventive medicine. He summarises and collates recent work on measurement of growth in children, infant mortality, the health of children in day nurseries, the unmarried mother and her child, problem families, and school medical inspection; and adds notes on psychosomatic illness, the adolescent in industry, and PULHEEMS. Dr. E. A. Cheeseman contributes a useful chapter on statistical methods. Professor Stevenson has a good eye for values, and in dealing with controversial topics—day nurseries, for instance—gives fairly the arguments of both sides before offering his own mature guidance. The book brings together much diffuse work, and presents a balanced view of the chosen subjects. The pity is that he has been obliged to confine himself to so few.

Fetal and Neonatal Death

(Revised edition.) EDITH L. POTTER, M.D., associate professor in department of obstetrics and gynecology, University of Chicago; FRED L. ADAIR, M.D., Mary Campau Ryerson professor emeritus in the university. Chicago: University of Chicago Press. London: Cambridge University Press. 1949. Pp. 173. 30*s.*

IN the nine years since this book was first written, interest in its subject has increased. It is divided into five sections—on the normal fœtus, post-mortem examination, causes of death, special pathology, and statistics. The section on post-mortem examinations is instructive. Too often the inquiry into the cause of death is perfunctory, with little attempt to find information of use to the obstetrician. A knowledge of obstetrics is indispensable to the pathologist examining these cases; yet even in quite large maternity hospitals the pathologist may be content to label infant deaths simply as "macerated fœtus," "tentorial tear," or "atelectasis"; while the "occasional pathologist" is liable to damage the cranial contents on opening the skull and to misinterpret his findings. The authors hold that this is a task for the specially trained pathologist whose interest extends both to clinical obstetrics and pædiatrics. More could have been said about neonatal infections as causes of death, particularly gastro-enteritis; and the statement that "the combined incidence of intracranial and abdominal hæmorrhage was only 1 in 5000 births," which they quote, is very hard to accept. The data on which this figure is based might well be critically surveyed.

Tuberculosis

A Global Study in Social Pathology. JOHN B. MCDOUGALL, C.B.E., M.D., F.R.C.P.E., F.R.F.P.S., F.R.S.E. Edinburgh: E. & S. Livingstone. 1949. Pp. 455. 32*s.* 6*d.*

EPIDEMIOLOGICAL study of tuberculosis is badly needed. The relative importance of the many factors which have combined to determine the downward trend of tuberculosis mortality in the past century is still matter for conjecture; the causes of retardation in decline in certain age-groups, in males or females, in certain communities or countries, are at present even more obscure. Dr. McDougall's book attempts to cover these problems; and if anyone is qualified to write such a book it is he, since, with his background of work in this country and his recent work in UNRRA and at the head of the section of tuberculosis at the World Health Organisation, he has collected a store of invaluable information on the subject.

He begins by presenting mortality-rates and other data from different countries, though the available information from many of them is very meagre. Next he discusses the factors influencing morbidity and mortality rates, under the headings of the vulnerable age-groups, variations between east and west, unrestricted migration, downward trends, native and acquired resistance, the infecting dose, and tuberculosis mortality in successive generations. In part III he discusses the task of investigating the tuberculosis problem in a community, and submits a schedule for its analysis. He comments on race, infection and morbidity, mass radiology (a long section presenting results from many countries), epidemiological surveys, environmental factors, and the organisation of tuberculosis services. The editing is unfortunately faulty (some of the forms are printed upside down, a "generation" curve for Sweden is given as for England and Wales, and vice versa, and in charts demonstrating the trend of mortality-rates over a period of years the scale is altered halfway across, without warning). It is inevitable that in so extensive a survey any reader will find points he disagrees with, and omissions; but Dr. McDougall has made a brave effort to cover the whole field.

Three Essays on the Theory of Sexuality (London: Imago Publishing Co. 1949. Pp. 133. 10*s.* 6*d.*).—Mr. James Strachey has worked with his customary fidelity and skill in preparing this first English edition of this work of Freud's, which has long occupied a most important place in the Freudian canon. He used the 1925 revision of the original, and had the help of Miss Anna Freud in ensuring that he should convey her father's meaning exactly.

Spectacle Fitting and Optical Dispensing (London: Hammond, Hammond & Co. 1950. Pp. 294. 30*s.*).—This essentially practical manual written by Mr. L. S. Sasieni for the student optician, describes the methods employed to ensure that a patient's spectacles do in fact sit on the face in such a way that the lenses do the work which the prescriber intended. The well-illustrated text is therefore chiefly concerned with facial measurements and types of frames, and it deals very fully with the subject. In another edition more prominence might be given to what may happen if the lenses are incorrectly sited. We should perhaps point out that, after severing the trigeminal nerve, spectacles are required not because the eye is more sensitive but because it is in fact quite insensitive and accordingly needs protection.

The book puts a mass of detail before the optician in readable form.

THE LANCET

LONDON: SATURDAY, MARCH 18, 1950

Hospital Finance

THE supplementary estimate presented to Parliament for the National Health Service is nearly £99 million, bringing the total cost to the Exchequer in 1950–51 to £358 million. In this unexpected £99 million the largest item is the additional cost of the hospital services—£41 million in advances to the regional hospital boards, and £7 million to the boards of governors of teaching hospitals. No doubt this represents mainly the restoration of the cuts imposed a year ago: and in that sense it may be said that the hospitals are, after all, only working to their own original estimates. But further increases lie ahead, and, at a time when reduction in Government spending is being so strongly urged, it will be asked why the Chancellor is allowing Mr. BEVAN to throw this colossal burden on to the taxpayer. What is the Treasury about?

The Minister of Health, we must hope, will not be induced to yield to any pressure for more rigid Treasury control of the kind already incipient. There is enough of this already. The trouble is rather that the system is wrong, and that, despite the rigidity which destroys the power to spend on the roundabouts what is saved on the swings, the money continues to pour out and hospital costs to soar. This is not perhaps surprising, for the Act did many strange things, whose full consequences have not been properly appreciated. The *Times* put its finger on the point last August when it said that:

> "The hospital service represents a notable innovation in social affairs. In it financial and managerial responsibility are divorced. The provision of funds is centralized, so that all hospitals can enjoy financial security, while management is entrusted to local committees, coördinated by regional boards, in order to preserve that flexibility and local touch essential for the welfare of patients and the professional freedom of doctors. For this novel experiment to work, the hospital management committee, subject to any necessary control by its regional board, must be in a position to count on a total annual sum, deemed adequate for its needs, which it is free to spend or save as it thinks fit. This is not what is happening. . . . The present makeshift methods were perhaps inevitable in the initial stages of a great social experiment. Their continuance may well wreck an experiment in the delegated management of a State service which was launched with the highest hopes."

Referring to the lack of a costing system, this editorial argued that such a system is an essential prerequisite to the delegation of spending power to match the delegation of administrative responsibility. In the 20th report of the Select Committee on the Estimates we have recently been told that something is in fact being done about a costing system. So far so good. But such a system by itself will not take us far; with it must be coupled the bold experiment in the delegation of financial responsibility for which the *Times* called.

The question to which Parliament should address itself is surely, what substantial reason is there why the principle of round-sum allocations should not be adopted? This principle was apparently endorsed when the Bill was in Standing Committee, for on June 27, 1946, the Parliamentary Secretary to the Ministry of Health, discussing the relevant clause, spoke of the regional hospital boards and the hospital management committees having "a considerable amount of latitude within the sum that has been approved." He went on to say that "quite obviously, if as a result of the activities of the year something unforeseen occurs and a deficit results, that deficit will have to be made good in the Budget arrangements for the following year; and also, if there is any surplus, that surplus must be carried through to the next budget period." He spoke of "a sense of real responsibility for the services they are providing, and for the finances of their administration." Why has the Minister gone back, or why does he appear to have gone back, on these assurances? Could it not be explained in simple language? It does not seem sufficient explanation that the vote for hospitals must be based on estimates and included with other items in the annual national budget; for the quite different principle of fixing a round sum or pool has been adopted in the case of the remuneration of the general practitioners.

It sometimes seems that the financial authorities concerned are strangely blind to the nature of hospital finance. What they seem to miss is the fact that in any hospital, at any time and any place, a really strong case can be put up for additional expenditure; and that, in the present state of society, against this advocacy no barrier erected by a lay authority, not even Parliament itself, can long prove effective if the question is merely one of voting the money. There is, of course, nothing new about this; but before nationalisation each hospital was a unit—or in the case of the local-authority hospitals part of a relatively small unit for limited finances—where one medical need clashed with another, and a great many, as it were, cancelled each other out. The financial authorities do not seem to have seen that it is to their own great advantage to grant the degree of delegation here advocated; as soon as they do, projects for expenditure will, for the first time since the appointed day, be fully exposed to rigorous and informed medical criticism. One claim will have to be compared with another, and some of them will look less convincing than they do today.

A system based on round-sum allocations would not only save the Treasury a large part of a steadily mounting bill but would, at the same time, rescue the hospitals from the strait-jacket into which they are now being gradually forced. To put it shortly, the hospitals *would fundamentally* rather have less money, and be free to spend it as they liked, than have to conform to a rigid "approved budget" and make every additional item they need the subject of an addition to estimates liable to be pruned from above. Doubtless, it would have been too difficult to introduce such a system right away on the appointed day; but with the knowledge of what the hospitals look like costing under the new régime it should be practical politics to say to each regional hospital board something like this:

> "Your budget for the next year [or three years, or five years, as the case may be] will be £*x*—excepting only that we will reimburse you for excesses brought about by circumstances outside your control, such as nationally agreed scales of salaries, or changes in the price level. Divide it up among your hospitals as rationally as you can, but not ignoring historic circumstances, and retain a modest pool at your own disposal for helping out where a hospital makes a good case for something extra. Meanwhile we shall do our best to get on with a costing system so that as the months go by you may have data to help you in deciding, by reference to comparative statistics, which hospital budgets will have to be reduced next time, and which can be allowed a little more."

A little too drastic, does it sound? Perhaps so; perhaps for quite a long while all sorts of exceptions would have to be permitted. But the principle is surely as right as the principles governing the present system are utterly wrong. The incentives would be right way up instead of upside down.

Vitamin B_{12} and Pernicious Anæmia

THERE *is now sufficient evidence for us to say that* preparations of vitamin B_{12} from liver or from *Streptomyces griseus* will produce a remission in pernicious anæmia, and that regular dosage will maintain a normal blood picture. UNGLEY,[1] who has reported results in 73 patients given vitamin B_{12} prepared from liver, found that small doses, such as 10 µg., produced a reticulocytosis but no satisfactory subsequent rise in red cells or hæmoglobin; in 32 patients the dose needed to raise the red-cell count above 4,500,000 per c.mm. varied from as little as 15 µg. to as much as 140 µg. Once the blood-count was normal, the average maintenance dose was 10 µg. fortnightly; only a few patients needed more. His 8 patients with neurological complications received much larger doses, 40 µg. being given weekly for up to ten months and then 20 µg.; the reason for this high dosage is not clear, but it is presumably based on previous experience with full doses of liver. The 8 patients recovered as well as they would have been likely to do on liver extracts, and so far there have been none of the relapses that followed folic acid treatment. Vitamin B_{12}, again unlike folic acid, causes the macrocytosis to disappear. Similar results on fewer patients were described by Dr. J. V. DACIE and Dr. J. N. M. CHALMERS[2] at the Royal Society of Medicine on Feb. 14. though they prefer larger doses. Unless some unexpected snag appears after longer experience, the practical value of vitamin B_{12} for the treatment of pernicious anæmia seems settled, and its everyday use is likely to be much increased by the production of a potent preparation from *Streptomyces griseus* at a price competitive with that of liver extracts. The estimation of B_{12} activity in these streptomyces preparations is far from simple, but there is much less uncertainty with them than in the assay of liver extracts, and manufacturers have complete control over their starting material.

The question now is, how does vitamin B_{12} work; what part, if any, does it play in the ætiology of pernicious anæmia? Since vitamin B_{12} was first obtained from liver, it is not surprising that it was soon claimed to be the "anti-pernicious-anæmia liver principle" in crystalline form; and it was then an obvious step to say that pernicious anæmia was due to a "deficiency," real or conditioned, of vitamin B_{12}. This view soon ran into difficulties. Several red cobalt-containing substances of the B_{12} type have been found in nature. LESTER SMITH[3] has separated three from liver; another streptomyces—*aureofaciens*—produces a B_{12} that has different absorption spectra from that produced by *griseus* but is hæmopoietically active in about the same dose.[4] HAUSMANN[5] has pointed out that B_{12} activity is widely scattered in nature, and that some of the materials—e.g., the cow-dung factor—are not hæmopoietically active until acted on by the enzymes found in hog-stomach mucosa or pancreas. Probably other "vitamins B_{12}" will be found; which of them is to be the liver principle? Then B_{12} activity has been found in animal foods—for instance, in meat[6]—but the quantities are small, and the amounts of vitamin B_{12} that must be given by mouth to produce any effect are far in excess of those likely to be provided by food.[7] When the excretion of vitamin B_{12} was studied, considerable amounts were found in the fæces, and by extracting the fæces and preparing the extract for parenteral injection it was shown that patients with pernicious anæmia were excreting hæmopoietically active vitamin B_{12} at a high rate.[8] Was it possible then that in *pernicious anæmia the vitamin* B_{12} in the food was not being absorbed in the small intestine? In this issue Dr. DYKE and colleagues show that the vitamin B_{12} is formed in the colon. They assayed the B_{12} in the contents of the alimentary tract of animals and man at various levels. In man an amount of the same order as is found in the liver was found only in the colon. In the horse, whose diet contains no B_{12} to speak of, the vitamin was again found only in the colon. The sheep, however, forms vitamin B_{12} in the rumen as well as in the colon. These findings suggested that vitamin B_{12} was being formed by bacterial synthesis in the bowel. In a review of this type of synthesis[9] we noted how many vitamins of the B group are known to be formed by bacteria in the bowel, and that in ruminants the same action occurs in the rumen—*the first stomach*, which we described as a veritable bacterial workshop. It is probable then *that the vitamin* B_{12} in human fæces is synthesised

in this way, and Dyke and colleagues have shown that some lactobacilli present in the intestinal contents can produce vitamin B_{12}. There is so far no evidence that vitamin B_{12} can be absorbed from the colon, and therefore the observations on fæcal B_{12} do not support the absorption defect theory.

Another approach was made by Castle and his co-workers, who set out to see whether vitamin B_{12} acted like an extrinsic factor in the reaction :

Intrinsic factor (hæmopoietin) + extrinsic factor → liver principle.

Some sources of extrinsic factor, like yeast, were known to produce irregular responses in pernicious anæmia when given alone, but if vitamin B_{12} was an extrinsic factor it was certainly more active than any previously isolated factor. Now the usual sources of intrinsic factor are human gastric juice or the press juice from hog-stomach mucosa. Castle therefore took a small amount of vitamin B_{12}, insufficient to produce any response by mouth, and mixed it with fresh unfiltered human gastric juice: the mixture was hæmopoietically active.[10] This observation has been confirmed, most recently by Ungley,[2] who considers that a mixture of 5 µg. of vitamin B_{12} with 50 ml. of human gastric juice has about the same hæmopoietic effect as 10 µg. of vitamin B_{12} given parenterally. But Dyke and colleagues incubated beef—a well-known source of extrinsic factor—with gastric juice and were surprised to find that the mixture had no B_{12} activity. The reason for this may lie in the observations of Ternberg and Eakin[11] that there is a factor in human gastric juice which combines quantitatively with vitamin B_{12} and then the vitamin is not available to micro-organisms. This gastric-juice factor, named "apoerythein," is heat-labile and non-dialysable: an identical factor can be obtained from hog-gastric mucosa, and in fact apoerythein has properties similar to those of Castle's intrinsic factor and Wilkinson's hæmopoietin.

At this point anyone familiar with the early work on the rôle of the stomach in the ætiology of pernicious anæmia might exclaim: "This is where I came in!" Twenty years ago Castle[12] and Wilkinson[13] showed clearly that gastric juice and beef muscle, hæmopoietically inert by themselves, produced a hæmopoietically active material when incubated together. This observation has been modified but never controverted. Castle and co-workers[14] later found that incubation was not necessary (the gastric juice and the beef could be given as long as 6 hours apart), and that a neutral reaction rather than an acid one favoured maximum hæmopoietic activity. Wilkinson and colleagues[15] concentrated their attention on the enzyme hæmopoietin that was readily available in the press juice from hog-stomach mucosa, and worked out the details of the reaction. The only work quoted in a contrary sense is that of Forminje[16]; but Forminje did repeat Castle's experiment and obtained the same result. He was chiefly interested in the extrinsic factor and showed that an 80% alcoholic extract of beef, from which fats and lipids had been removed, still contained extrinsic factor and produced a hæmopoietically active material when incubated with gastric juice. The only point of difference was that his product was inactivated by 70% alcohol, whereas Wilkinson's was not.

Any practical hypothesis about the ætiology of pernicious anæmia must take into account the invariable achlorhydria and failure of secretion of the gastric enzymes, including intrinsic factor. Vitamin B_{12} certainly has properties resembling known extrinsic factors; is it the only effective one? We do not yet know: Ungley's reminder[2] that yeast, a very potent source of extrinsic factor, has no B_{12} activity, suggests that vitamin B_{12} is not the only source. Ten years ago we might have thought that only a little tidying up remained to complete our knowledge of the ætiology of pernicious anæmia. Folic acid and vitamin B_{12} have changed all that, but the early emphasis on the fundamental importance of the gastric lesion still stands: it is our ideas on the later stages that are likely to be expanded and clarified by the researches now in progress.

Surgery of Carcinoma of the Cardia

The classical description of the lymphatic drainage of the stomach, by Jamieson and Dobson[1] in 1907, presented technical problems in the treatment of gastric cancer which were then insoluble, and the surgeons of the time had no choice but to ignore its lessons. In those days the only surgical approach to the stomach was through the abdomen, and if a carcinoma could be resected with a reasonable margin of apparently healthy stomach it was the most that could be achieved. But a glance at the diagrams of Jamieson and Dobson must have shown that such a partial resection cuts across the lymphatics in a way which would not be tolerated in the treatment of more accessible cancers. The lymphatics of the lesser curvature and upper part of the body of the stomach pass up to the cardia and over the fundus into the left gastric and suprapancreatic glands. That these vessels were severed and the gland stations left behind was regrettable but unavoidable. So, though an occasional patient survived resection for a long time, any statistical survey of the results was bound to be depressing. A few highly skilled surgeons tried to improve the results by performing total gastrectomy with œsophagojejunostomy, but even in their hands the operative mortality was formidable. Carcinomas starting high up in the stomach and involving the cardia were rejected as inoperable, apart from palliative gastrostomy or jejunostomy. These measures did little to relieve discomfort or to prolong life, though there were inevitably a few patients so treated whose symptoms arose not from a carcinoma but from a stenosing peptic ulcer of the stomach or œsophagus, and these patients were saved.

The modern achievements in the surgery of upper growths of the stomach are largely the outcome of advances in anæsthesia, chemistry, and physics. Safe blood-transfusion and chemotherapy removed two of

[illegible]

the main obstacles to the extension of surgical techniques; and the ability of the anæsthetist to keep a patient in good condition for 3–4 hours with his abdomen and both pleural cavities open made it possible to attack these growths from the chest. Carcinoma of the cardia, which for no known reason is twice as common in men as in women, may be a primary gastric growth involving the diaphragmatic œsophagus and even extending high up into the mediastinum, or it may be a squamous carcinoma of the œsophagus extending down to the cardia and over the gastric border. The approach from the chest, with incision of the diaphragm and delivery of the growth up through the chest, soon gave place to a combined thoraco-abdominal approach, and most surgeons would now agree that this direct exposure is the only satisfactory one. The extension of the incision across the costal margin, with splitting of the diaphragm in the same direction backwards into the œsophageal hiatus, gives an exposure through which the growths can be extirpated whether they extend high into the œsophagus or low into the stomach. To dissect the pylorus and the hilum of the liver is as easy as to remove mediastinal lymph-glands. This may well be the incision of choice for all gastric carcinomas, except perhaps those at the extreme pyloric end invading the pancreas. The local resection of growths at the cardia has presented no great difficulty and has been valuable in relieving dysphagia; but it soon became obvious that the recurrence-rate after such limited operations was very high, and that a far more extensive radical operation was called for.

Physiology as well as anatomy must be considered in planning an operation for carcinoma of the cardia. The physiology of the cardia is not yet fully understood, but we know that it cannot be disturbed with impunity. Normally the œsophagus, which has a relatively poor resistance to the digestive juices, is protected from them by the mechanism of the cardia. The oblique entry of the œsophagus into the stomach, the oblique fibres of the stomach arching over the cardia, and the thick tunnel of the diaphragmatic crura through which the lower œsophagus passes, all combine to prevent the reflux of acid and food from the stomach into the œsophagus. During belching and vomiting, of course, this arrangement is relaxed, and persistent vomiting may lead to erosion of the œsophagus. If, however, the anatomy of the cardia is disarranged, either by its herniation into the mediastinum or by surgery, there is a serious risk of erosion of the œsophagus. It is still impossible to predict which patient with a sliding hernia of the cardia will develop such erosion; this certainly does not wholly depend on the amount of acid in the stomach. The danger of œsophageal erosion must be borne in mind when restoring the continuity between the œsophagus and the stomach after resection of the cardia. The operation of resection with mediastinal œsophago-gastrostomy reproduces the condition of sliding hernia of the cardia, and would therefore be expected to cause œsophagitis, œsophageal ulceration, and even stenosis in some cases. Postoperative œsophagitis with heartburn and waterbrash does in fact occur; later there may be chronic œsophageal ulceration and fibrosis with dysphagia, and the ulcers have even perforated the aorta, the pleura, and the pericardium. But so far no-one has published a detailed follow-up report on a big series of œsophagogastrostomies to tell us how often these more serious complications arise. Many surgeons think the milder digestive disturbances a small price to pay for the removal of a malignant obstructing growth, and the Americans who have practised the operation extensively seem well content with their results. The alternative is to anastomose the œsophagus with the jejunum. If a carcinoma of the cardia is resected with enough œsophagus to give a good margin of healthy tissue beyond the growth it is impossible to bring up a loop of intestine and anastomose it to the œsophagus, as is done in partial gastrectomy. If this form of anastomosis is done, the œsophagus will inevitably be resected too low down. Œsophagojejunostomy therefore necessitates a plastic operation on the mesentery, as in the method of ROUX.[2] The œsophagus is then anastomosed to the end of the jejunum, and continuity is restored by a "T" anastomosis lower down. After this there is no reflux of biliary and pancreatic fluid into the œsophagus to produce œsophagitis, and the method allows of the whole stomach being removed.

Histological examination of the stomach wall some way from the apparent margin of a gastric carcinoma often shows microscopic involvement, and some surgeons believe that a total gastrectomy is the best treatment for all growths involving the stomach. Growths of the cardia, whether they are squamous growths of the œsophagus or glandular growths of the stomach, may spread to involve the left lobe of the liver, the spleen, the pancreas, the left suprarenal capsule, or the diaphragm. The thoraco-abdominal approach makes it possible to resect such growths with their extensions, and it is probably wise to remove the adjacent part of the diaphragm in all neoplasms which transgress the cardia. There is direct or indirect lymphatic drainage from the stomach into the hilum of the spleen, over the fundus of the stomach into the retroperitoneal tissues, and so to the supra-pancreatic glands. Even where the pancreas is not directly involved, the lymph-glands along its upper border and posterior surface may well be affected. A radical dissection, therefore, necessitates removal of the spleen and most of the body of the pancreas, with retroperitoneal tissues extending up from the pancreas to the hiatus.

Recent work in this country has convincingly shown that the lymphatic vessels and glands which JAMIESON and DOBSON described are, in fact, those involved in gastric carcinoma. The surgical treatment of this disease, therefore, is now at the stage where carcinoma of the rectum was about twenty years ago. Some surgeons still prefer a relatively local resection with a low mortality to the more extensive but theoretically sound operation which may carry a higher mortality. With carcinoma of the rectum, the operation which was theoretically sound ultimately found favour, and it seems likely that the same will happen in the case of the stomach. Meanwhile, whatever line of attack the surgeon chooses, he should keep accurate records of what he has done, with a careful follow-up, so that in ten years' time our conclusions will be decisive.

Annotations

CORTISONE AND A.C.T.H.

THE dramatic results achieved with 'Cortisone' and adrenocorticotropic hormone have fixed our attention on the adrenal gland; and we have thus tended to lose sight of the interdependence of this and other endocrine organs. Elsewhere in this issue Dr. Long and Dr. Miles, of the National Institute for Medical Research, develop the evidence for a balanced opposition between thyroid and adrenal hormones. Their article is also notable for containing the first report on work carried out in Britain with cortisone.

In the U.S.A. the Mayo Clinic workers[1] have brought together and extended the clinical and biochemical data on both cortisone and A.C.T.H. They have confirmed the capacity of cortisone, administered in sufficiently large doses over a long period, to induce most of the clinical and metabolic features of Cushing's syndrome. The features induced in this way include rounding of the facial contour, hirsutism, acne, keratosis pilaris, muscular weakness, œdema, amenorrhœa, cutaneous striæ, mental depression, impaired carbohydrate tolerance, negative nitrogen balance, increased excretion of corticosteroids in the urine, and hypochloræmic hypopotassæmic alkalosis. Both cortisone and A.C.T.H. have been found to promote urinary excretion of creatine and uric acid, and to give rise sometimes to a negative potassium balance. Their effects on sodium and chloride balances are variable, the usual pattern being retention, followed by increased excretion, of salt; sometimes urinary excretion of calcium and phosphorus is slightly increased. The report provides further evidence that protracted administration of cortisone depresses adrenal cortical function; and the Mayo Clinic group suggest that the 17-ketosteroids excreted during its administration are derived largely, if not entirely, from the cortisone. It seems that A.C.T.H. stimulates the adrenal cortex to secrete, not cortisone (17-hydroxy-11-dehydrocorticosterone), but the closely allied Compound F (17-hydroxycorticosterone).

Injection of pituitary thyrotropic or gonadotropic hormone is well known to induce in animals of heterologous species a refractory state associated with demonstrable anti-hormones in the serum. That this reaction extends to A.C.T.H. has been demonstrated, in the rat, by Chase[2]; and her report has been followed by one from Gordon[3] showing that rats gradually became refractory to hog A.C.T.H. in doses comparable, on a body-weight basis, to those used in man to alleviate rheumatoid arthritis. It has already been established that continued injection of pituitary extracts from heterologous species may render animals refractory to their own pituitary hormones, with subsequent atrophy of the "target" glands[4]; and Gordon concludes that "one might speculate as to the possible effect of antihormone on the pituitary-adrenal system of a refractory animal or patient who continues to receive heterologous A.C.T.H." As time goes on, we are likely to see still more clearly how right the initiators of the method have been in insisting that A.C.T.H. and cortisone, must for the present be regarded as research tools rather than sure means of treatment. The national councils advising the United States Public Health Service on medical-research problems have in fact urged that both drugs should be used only for reseach; and that most of the basic reseach on treatment, side-effects, and mode of action should be made with animals.[5]

BLOOD IN THE STOOLS

THE passing of blood in the fæces is a common feature of disease. It must always be regarded seriously because all its common causes, except internal piles, are serious. The blood may be obvious or it may be occult and detected only by special methods. Melæna means the passage of a shiny black (μέλαινα = black) tarry stool, consisting largely of partly digested blood, but the term is often applied loosely to any passing of blood from the anus. Bleeding in the upper part of the bowel, including the small intestine, usually produces melæna, and as little as 50–60 ml. of blood will render the stool black.[1] Red blood in the fæces usually indicates bleeding from the colon, rectum, or anal canal.

The diagnosis of the cause of blood in the stool is the diagnosis of alimentary disease. It rests on careful routine history-taking, complete physical examination, and the results of investigations. In every case there are two questions to be answered: (1) "What is the site of the bleeding?", and (2) "What is the pathological lesion?" In the history other symptoms must be noted. Hæmatemesis commonly precedes melæna when the œsophagus, stomach, or duodenum is bleeding. There may be a typical ulcer dyspepsia, but this is not invariable in cases of bleeding peptic ulcer. If there is colic and diarrhœa, with mucus as well as blood in the stools, enteritis or colitis is probably the cause. If there are symptoms of large bowel obstruction, with streaks of red blood in the stools, the most likely lesion is a carcinoma of the pelvic colon or rectum. The physical examination must include a search for evidence of general systemic disease such as purpura or uræmia. There may be an obvious source of bleeding in the mouth or nose: splenomegaly may suggest bleeding from œsophageal varices; and so on. Rectal examination, which must be done in every case, may reveal an anal polyp or fissure, or a carcinoma of the rectum. The finger should always be examined for blood after it is withdrawn. Piles can only be diagnosed by proctoscopy unless they are prolapsing or thrombosed. Internal piles are the commonest source of blood in the stool, but we must remember that the piles may be secondary to pregnancy, portal obstruction, or carcinoma of the rectum. Anyone who complains of piles for the first time over the age of 40 should be examined with a sigmoidoscope. Many cases of bleeding per anum will need further investigations. Radiography with the barium swallow, barium meal, and barium enema can be very helpful. Sigmoidoscopy is essential for the examination of the rectum and pelvic colon, but œsophagoscopy and gastroscopy are usually reserved for cases in which the X-ray findings are inconclusive. The fæces must be examined for pathogenic bacteria and for amœbæ when an infection is suspected. Blood diseases, hæmorrhagic states, enteric infections, and uræmia, all of which may cause intestinal bleeding, can be detected by blood examination. In a few cases, especially when bleeding is the only symptom or sign, the cause will remain obscure. These must be followed carefully and re-investigated if the bleeding is repeated or if new features develop. Occasionally laparotomy is necessary to establish the cause, and more rarely it has to be done urgently to stop bleeding from an unknown source.

In the U.S.A., Thompson and McGuffin[2] have analysed 293 consecutive cases with blood in the stools as a prominent feature, excluding those in which the bleeding was in the anal canal. Peptic ulcer accounted for 30% of the cases, and, though 80% of these had hæmatemesis at some time, the blood appeared *first* in the stool in 62%. Next came bacillary dysentery with 21% of cases, most of them in children, while non-specific enteritis and colitis accounted for less than 1%. In Britain there are

probably fewer dysenteric and more non-specific cases of enterocolitis. Œsophageal varices (9%), carcinoma of the stomach (8%), carcinoma of the rectum and pelvic colon (6%), idiopathic ulcerative colitis (5·5%), diverticulitis of the colon (4%), and uræmic colitis (3%) came next in frequency. Intussusception was the cause of only 1·4%, and there were no examples of blood diseases. Lesions of the small intestine, which formed only 2% of this series, are rare in most people's experience, though from time to time Meckel's diverticulum, Crohn's disease, mesenteric thrombosis, and tumours of the small bowel do cause bleeding without much other evidence of their true nature. The causes of small intestinal bleeding have lately been reviewed by Hodes and Edeiken.[3]

Tests for occult blood in the stools have fallen into disrepute in some quarters, but their results may be valuable if they are interpreted critically. Bleeding gums and piles, and meat in the food, may give positive reactions, and constipation may cause false *negative* results.[4] When using the benzidine test a meat-free diet for at least two days is essential, and the stools must always be examined for meat fibres. The test should be done on at least three separate occasions. Hoerr and colleagues [5] favour a modification of the guaiac test, easily performed in the consulting-room. This is not sensitive enough to be affected by meat and can therefore be done on outpatients, provided they are not taking iron. While negative reactions are unreliable, they claim that positive guaiac reactions denote significant organic bleeding in a high proportion of cases. The test is simple:

> A smear of fæces (from a fingerstall) is placed on a filter paper, and one or two drops each of guaiac solution, glacial acetic acid, and hydrogen peroxide, in that order, are placed near the fæces. If a blue or dark green colour appears within 30 seconds the result is positive.

Dunphy [6] reports 2 cases of resectable carcinoma of the small intestine which had produced positive guaiac reactions but could not be demonstrated by routine radiology. In each case a Miller-Abbott tube was passed until a level was reached from which the aspirated samples contained occult blood. That part of the bowel was then filled selectively with barium through the tube, and the lesion was demonstrated radiologically. This rather complex test will be worth the extra trouble if it will locate even an occasional growth of the small gut at a curable stage.

PENETRATION OF OVUM BY SPERM IN VITRO

EARLY in 1948 Menkin and Rock [7] announced that they had obtained fertilisation and cleavage of human ova removed from ovaries by dissection in vitro under aerobic conditions. They had made the attempt 138 times and had obtained cleavage in 4 ova. This caused a stir in the popular press; but more sober observers were not so readily convinced, and Rock himself admitted that parthenogenesis could not entirely be ruled out. After working on the subject for several years, Moricard and Bossu [8] report that their attempts to obtain fertilisation and cleavage of rabbit ova under aerobic conditions, as described by Menkin and Rock, were invariably negative in 60 cases; the spermatozoa never succeeded in penetrating the membrana pellucida. But, when rabbit spermatozoa and ova were brought together under relatively anaerobic conditions in the presence of tubular epithelium and seminal plasma, penetration occurred every time in 8 cases. By cutting serial sections they have observed and demonstrated the very earliest stages in the process of fertilisation. They believe that their technique will be applicable to human spermatozoa and ova, and, if so, this will mark a definite step forward in the struggle to unravel the complex physiology of mammalian ova, spermatozoa, and tubular epithelium.

FLUOROSCOPIC EXAMINATION OF THE CHEST

IN the early days of radiography "screening" was used freely in diagnosis; but as films became easier to take it dropped into the background. It is so pleasant and convenient to be able to back one's opinion with a permanent record that the temptation to ask for a film is very strong, both for the physician and the radiologist. However, things have reached such a pass that our X-ray departments are congested by the amount of work pouring into them, and our task is now to think of ways of lightening the load. Dr. Stephen Hall and Dr. William Tattersall, on another page, advocate a return to a much wider use of fluoroscopy. Not only would this save time and money, but it would also, they suggest, give information which could not readily be obtained in other ways. Thus it is possible by changing the tilt of the patient's body, and by making him bend, breathe deeply, or pant, to estimate the depth of various shadows, and to avoid some common pitfalls of diagnosis from the film. Fluoroscopy, they say, differs from inspection of the film in the same way that cinephotography differs from still photography; and they have found that the information it gives tallies well with that to be expected of the fixed film.

Fluoroscopy has its drawbacks however, one of them being that radiologists, like other people, differ in their powers of dark adaptation. Hall and Tattersall suggest the use of dark glasses to enable the radiologist to go on working while his visual purple is collecting; and evidently they are themselves both capable of good adaptation. But, as Mr. Cecil Ashwin, M.S.R., has pointed out,[1] in a review of prevailing opinion on the value of fluoroscopy in tuberculosis case-finding, "the ability of an individual to see in the dark depends on many factors such as temperament, physiological condition and vitamin intake: further, this function can vary from day to day." This variability probably accounts for the large body of opinion he is able to report *against* the value of fluoroscopy. He quotes Garland, who put the percentage error in the detection of tuberculosis with this method (as compared with radiography) between 13 and 35; Fellows and Ordway, from a study of 2500 cases, agreed with this figure, and Voigtlander, from another 2500 cases, concluded that in 32% the diagnosis by fluoroscopy was either incorrect or insufficient. Schaare found an error of 18% in fluoroscopic findings; while Edward and Ehrlich, after reviewing mass surveys of 100,000 people, decided that the drawbacks of fluoroscopy outweighed the advantages. Ashwin quotes other opinions of the same kind, but sets them against an equally weighty set of favourable reports.

It seems that if fluoroscopy is to be widely used we need some method of testing the accuracy of the observer. A test of visual adaptation in darkness has been devised by Chantraine and Cramer, which consists, Ashwin says, in enumerating, from a fixed distance, lead numbers of various sizes mounted on a standard fluorescent screen. Of 30 doctors tested in this way, only 6 were "good," 10 were "medium" and 14 were "poor." Two-thirds of them needed more than ten minutes to attain minimum dark adaptation. Ashwin suggests that patients should be sieved first by mass radiography; and that suspected cases should then be fluoroscoped by a capable observer, and a spot film taken of any suspicious area. This would enable the preliminary sifting to be done in the absence of the radiologist, and would make a full-size film necessary only in exceptional cases. Hall and Tattersall believe that screening alone can safely be used to exclude tuberculous lesions and will thus save many films which are at present wasted.

DENTAL CRISIS

ALEXANDER MACGREGOR
M.A., M.D. Camb., F.D.S. R.C.S.

THE dental part of the National Health Service has now been in operation for 1½ years, and even the most sanguine must concede that all is far from well. The dental profession, as a whole, has cooperated loyally, despite the fact that suggestions forwarded by the British Dental Association have consistently been ignored. It is true that a few unscrupulous practitioners have seized the opportunity to feather their own nests at the public expense, and such cases have received considerable publicity; but on the whole the profession has done its best to cope with the enormous amount of work that has accrued. Nevertheless we are clearly approaching a situation detrimental to profession and public alike.

QUALITY OF WORK

Dental surgery involves long hours of meticulous concentration, and the operator is additionally fatigued by dealing constantly with patients who are themselves in a state of nervous tension and require a continuous effort on his part to allay their fears. Whereas the general surgeon operates almost always with some form of anæsthetic, the dental surgeon doing conservative work has to be continually on his guard against hurting the patient, and is ever on the watch for the involuntary movement that betrays the fact that the drill is reaching a sensitive part. This applies, of course, chiefly to conservative dentistry; but conservative dentistry forms, or should form, the bulk of the average dental surgeon's practice.

To set against this, there is the pleasure obtainable from good craftsmanship skilfully applied, and in the higher flights of conservative dentistry not only precision but fine craftsmanship is needed. The preparations of crowns and bridges is arduous and exacting, but fundamental satisfaction comes from doing the difficult job well. In the field of prosthetic dentistry, the fitting of skeleton metal partial dentures—which as regards oral hygiene are far preferable to those made of vulcanite or acrylic resin—again takes time and skill, as well as more expensive materials. The extra time and trouble required to secure a perfect match of artificial teeth to natural teeth, and the arrangement of artificial teeth to assume a natural appearance rather than the even row of white teeth only too often seen, are well spent for the satisfaction obtained by the man who views his work as something more than oral plumbing.

In an endeavour to keep this sense of craftsmanship alive, the British Dental Association have, from the first, advocated a system of grant in aid. In effect, this would mean that patients requiring special work should be allowed to pay extra for the time and trouble involved, over and above the basic fees paid by the Ministry. The Ministry, however, apparently thought that this system would lead to abuses, and it has been consistently refused.

For the average dental surgeon working under the scheme there is, therefore, little incentive to do work requiring extra time and skill, and his incentive is bound to become more and more financial. Since its inauguration, patients have been flocking to the dental surgeries, and busy practitioners booked up for months in advance are quite unable to undertake anything beyond the routine procedures necessary to get the greatest number of patients treated in the shortest possible time. All agree, of course, that it is important to provide a service for the country as a whole, and that of necessity large numbers of patients have to be treated. The emphasis has, however, come to lie more on quantity than quality, which cannot be in the ultimate interests of the public, and must lower the respect in which the British dental profession is at present held.

SHORTAGE OF DENTISTS

It is not generally appreciated that the number of dental surgeons in this country at the moment is totally inadequate. With fewer today than in 1939, the profession is understaffed and overworked.

The most serious effect of the new scheme has been to withdraw dental surgeons from the services provided for the priority classes, especially for children. In almost every part of the country the school dental services are incapable of providing proper treatment. For example, in the Middlesex area, where the establishment is for 96 school dental officers, there are at present 51, and fully equipped surgeries are lying idle with no-one to work in them—this at a time when over 70% of London County Council school-children of the age of five are suffering from some degree of dental caries.[1] It was to be a leading principle of the National Health Service that the future generation should have the best possible attention. This attention, from the dental point of view, they are not receiving.

It is clear that action is urgently required if the scheme is to succeed—and all are agreed that some scheme is necessary and must be made to succeed. Can we get new recruits to the profession in time? Can we indeed get them at all if they know that immediately upon qualification they will enter a career where fillings have to be turned out in quantity daily, with little to alleviate the monotony?

Ross [2] has suggested that, in order to meet the present crying need for treatment for children, dental practitioners in the N.H.S. should give up some hours each week to their treatment. This, however, would certainly mean some reduction in the time given to adults, and it is hard to see how it could be arranged when practitioners' appointment-books are full for months ahead.

SALVATION BY ANCILLARIES?

The alternative is the employment of ancillary workers within the profession. This, though it has on the whole been resisted by dental surgeons, might in the end prove of great benefit. If routine fillings were done by such workers in a clinic under the supervision of a qualified dental surgeon, far more work could be undertaken, and the number of qualified men required proportionately decreased.

Admittedly the preparation of a cavity in a tooth, removal of dental caries, and the insertion of a filling require a knowledge of the reactions of the tooth, as well as of its anatomy and the physiology of its repair. In addition, manual dexterity and a knowledge of technique are clearly needed. But such work does not, in my opinion, demand the fundamental knowledge of physiology and pathology expected of the medical and dental student.

In the dental hospitals, and in dental departments of teaching hospitals with an attached dental school, the bulk of the work is carried out by students under the supervision of a qualified staff. The introduction of the National Health Service caused some anxiety to those responsible for training dental students, on the grounds that the numbers of patients attending hospitals might diminish, and that they would want to be treated by the qualified practitioner rather than by the unqualified student. Fortunately these fears have not been realised, and the numbers attending the hospitals have greatly increased. At the Royal Dental Hospital of London, for example, patients attending in 1949 numbered almost 24,000 more than in 1947.

Patients judge a hospital by the treatment that they receive in it. They are fully aware that their treatment

---

1. Mellanby, M., Coumoulos, H. *Brit. med. J.* 1946, ii, 565.
2. Ross, W. S. *Brit. dent. J.* 1950, 88, 15.

is being carried out by unqualified students, yet their attendance signifies their satisfaction. If they are satisfied with the treatment given by unqualified dental students working under qualified supervision, why should they not be satisfied with the treatment given by ancillary workers specially trained in the necessary techniques, also working under qualified supervision ?

A precedent has been set in New Zealand, where dental nurses, trained but with no degree, undertake children's dentistry including fillings and extractions. The scope of the work which they are allowed to do is limited, since not infrequently they are working by themselves in isolated communities where they cannot easily get the advice or assistance of a fully qualified dental surgeon. At the same time the fact that they can undertake this work at all means that fewer qualified men are needed, and that more children can have adequate routine treatment.

If children's dentistry were to be undertaken mainly in special clinics many difficulties could be avoided. The course for the unqualified assistants, who would do no more than fill teeth, need not be so long as it is for the New Zealand nurses, who need rather wider knowledge. The unqualified assistants would be under constant qualified supervision.

If in a dental school one qualified demonstrator can supervise twenty students (at various stages of training), and if each student can finish two fillings in three hours, one qualified man can be responsible for forty fillings during this time. Clearly a much larger number could be dealt with by assistants trained in conservative technique and no longer working with the slowness of the student.

The training of the large body of assistants who would be needed to cope with the present situation presents certain difficulties. The dental schools in this country, already too few and too small, can scarcely handle their present students. It must be remembered, too, that increasing the number of dental students not only necessitates enlargement of the departments of the dental school but also throws an extra burden on the preclinical departments of the universities and medical schools, which are already overtaxed. For this reason entries to the medical and dental schools have had to be limited.

One incidental but grave result of this is that the more ambitious dental student who wishes to obtain both a medical and a dental degree is finding it almost impossible to get a medical school to accept him. He is told that a student who obtains his dental qualification is capable of earning his own living and should not take up the space and facilities needed for the training of his medical colleague. At the moment, this argument cannot be lightly swept aside ; but what a deplorable outlook for the profession ! Dentistry has had its dark ages when oral physiology and pathology were regarded as subject to laws different from those applicable to the rest of the body ; and the conception that dental surgery was but a specialised branch of medicine has had a tardy period of gestation. But the desirability of having the wider knowledge implied by the possession of a medical qualification is shown by the fact that the larger teaching hospitals demand that applicants for senior dental staff appointments should be qualified in medicine as well as dentistry. Where are such men to come from in the future if the present impasse is allowed to continue ?

Technicians undergoing training would probably derive some benefit from a short preclinical course, but this need not be long, and the main emphasis would be placed on purely technical training. The period necessary for this is hard to assess ; but, given an entrant with reasonable inherent manual dexterity, at the end of one year he or she should be able to undertake the normal routine cutting of cavities and filling of teeth. The shortness of this period of training, compared to the five years necessary for the dental student proceeding to the licence or degree, means that a large number of such technicians could be produced fairly quickly once a training scheme had been started.

To find centres for this training is not easy. The dental schools would not be able to accommodate any substantial number of such trainees without severe disorganisation of their present curricula and consequent disadvantage to their own students. Yet some association with existing schools would be necessary to ensure the supply of necessary patients. The difficulty, however, is not insuperable ; it could be overcome by the addition of special departments to selected hospitals or the adaptation of large existing clinics.

Such proposals in the past have been vigorously opposed by the dental profession, who fear that the entry of unqualified assistants would lead to numerous abuses. But some remedy for the present situation must be found, and if such technicians were given an adequate course of training, were properly paid, and were set to work under the supervision of qualified men, the man-power problem could be solved.

The fear of many practitioners, with the lesson of the pre-1921 era before them, has been that once unqualified assistants were recognised, not only might there be abuses, but in addition their livelihood might gradually be taken from them. Is this fear well founded ? Status has always been a sore point with the profession. Dental surgeons have felt that they were not regarded as having the same standing as medical practitioners ; the public has not regarded them as specialists in the mouth, jaws, and teeth but rather as makers of plates and fillers of teeth. But if ancillary workers were to be admitted to the profession—in the first instance to carry out fillings and possibly later to make and fit dentures—the result must inevitably be an elevation of the status of the dental surgeon, who would more and more come to be regarded as a specialist. In the end, indeed, the possession of a medical as well as a dental degree might be required of him, thus putting dentistry on a level with the other medical specialties. How much better for the embryo dental surgeon to envisage a career in which he is able to exercise his knowledge and his judgment, and does not become a mere automaton with a drill in one hand and extracting forceps in the other.

Some answer to the problem of the children must be found, and found quickly. It is intolerable that a health scheme in which they were rightly to be given every priority should have resulted in their receiving less treatment than ever before. The school dental service as at present constituted is moribund, and there is little if any chance that, before the last rites have to be administered, it will be revived by the large number of dental officers it urgently needs to bring it up to strength.

The time has come for both the profession and the Minister of Health to face these facts. Bold decisions have got to be taken, and they must be taken *now* before it is too late.

" . . . The concept that the biologic rôle of the father ends at the moment of impregnation is not correct in the case of the human young. Psychologic growth is a biologic function and the child is in need of an affective and warm father. This is especially true for the boy, who needs a father figure who is close enough to permit a positive masculine identification. In our culture, however, the father is very often a remote person who leaves the house early in the morning, often returning only after his small children have already gone to sleep ; on weekends too, he is either " tired " or too preoccupied with his own affairs to find time enough to pay much attention to the children. Many fathers . . . think that they are good and modern husbands if they leave all questions pertaining to the education and discipline of their children to the mother, to be consulted only in emergencies and as a kind of executioner to apply punishment."—Dr. WILFRED C. HULSE and Mr. LOUIS LOWINGER, *Amer. Pract. Dig. Treatm.* Feb. 1950, p. 139.

DANIEL WHISTLER, P.R.C.P. 1683

AN EARLY DIRECTOR OF NAVAL MEDICAL SERVICES

A MAN who makes a great stir in the world will have many biographers, some of whom may blame while others praise him. So Sir Francis Drake, shining in the pages of one as a perfect knight, appears in another's a common pirate; or King Charles II, whose morals for centuries have been exhibited as questionable, is now shown to us as a man of high virtue whose portrait might well hang in the offices of the Young Women's Christian Association. The range is considerable and the reader can use his judgment. But of those who have made less bustle in the world we are given but a few lines in a book of reference, or maybe a footnote in the Life of some illustrious person. Usually we have but one man's opinion and we know not whether it is right or wrong.

In books of reference the name of Daniel Whistler, M.D. Leyden and Oxford, stands for one who wrote the first printed book on rickets and came in the end to high office in his profession with little credit to himself, being written down as a negligent registrar of the Royal College of Physicians and as a president careless—or, worse—of its property. It is perhaps revealing that the name he proposed for rickets was "pædossplanchnosteocaces." Yet dull as he may have been on rickets and reckless as he may have been when he came to office, two of his contemporaries thought well of his abilities and found him good company: Evelyn in his *Diary* wrote of him as learned and "the most facetious man in nature," by which he meant urbane; while Pepys often notes "a good discourse" or "an extraordinary good discourse" with him on subjects ranging from Ancient Egypt to the preservation of masts. There is one subject however not mentioned in either diary on which we may be sure the three men held good discourse, and that was the care of wounded men, for in this all three were deeply interested. During the first Dutch war Cromwell had placed Whistler, then but 34 years of age, in charge of naval medical services, while in the second and third wars Evelyn was a commissioner for the care of sick and wounded and Pepys was Secretary of the Admiralty. Of course the testimony of the diaries hardly goes further than to show Whistler as a good talker. It is the State Papers which make it clear that he was something more.

THE FIRST DUTCH WAR

On his arrival in Portsmouth, in March, 1653, Whistler found the wounded had been pouring in for some time from the fight off Portland; and, there being no naval or civil hospital for their comfort, they had been of necessity scattered all over the town and countryside, in ale houses and hovels. He wasted no time. In reporting the taking up of his appointment to the Council of State, Whistler says he had already returned the slightly wounded to their ships "where salt meat will not do more hurt than strong drink will do here"; while the severely wounded, and those who had lost limbs and consequently were of no use for present service, were on their way to the London hospitals in horse waggons, 8 cases in each, with sufficient surgeons and nurses to take care of them. A grim and wearying journey it must have been for those badly damaged men, as the lumbering waggons climbed Portsdown and jolted and slid over Butser Hill; the ways would have been foul, for it was March. He goes on to say that, notwithstanding the double evacuation, the town was still choked with wounded, and in consequence the sick from the Fleet were being landed at Fareham, signs of malignity in the sickness making this the more advisable.

Five days later he is writing again to the council on the desirability of establishing a naval hospital for the port. He first points out the inconveniences of the boarding-out system, leading to shortcomings in treatment: how sick and wounded were left lying long on the ground until owners of houses would come to terms, and often had a long wait before the surgeons were told of their location: there was the want of linen and medicines which should be ready to hand, besides the difficulties of dieting and nursing: the crowding of weak men into "poor stifling houses": the temptations to them of "drinking inordinately in victualling houses who have no other but strong drinks." He ends by saying that he reckons "the expense of one man scattered, if to the satisfaction of his host, is so much as I believe would suffice two in a hospital."

Whistler was likely to have been unpopular with the publicans, for, though the Government allowance for board and lodging was only 7s. a week, the presence of a wounded man in the bar parlour must have been a great attraction. From time immemorial the controlled price for the exhibition of a cut finger has been the bite of an apple; one trembles to think what the price in cans of beer would have been for the display of a sawn-off leg. It is easy to appreciate Whistler's anxiety to get such cases away to a place where beer did not flow quite so torrentially and amputations were at a discount.

THE NEED FOR A HOSPITAL

Naturally with all these drawbacks he was all for "some one place, capacious and not ill situated in respect of air, water and conveniency of landing," and all these qualities were to be found at Porchester; but he questioned whether it would not cost as much to repair an old ruin as to build a new house. Attempts were made to acquire the castle, for the need was urgent; but the owners asked more than the Admiralty were inclined to pay, and the battle smoke soon after rolling away out of the Channel into the North Sea, the urgency passed, and Porchester Castle still stands as a brave old ruin at the head of Portsmouth Harbour.

The idea of building a new house was not Whistler's own. Before the arrival of the wounded, Francis Willoughby, the commissioner of the port, had suggested the building of a house to cost about £300, with a man and a woman belonging to it at a small salary, and a superannuated surgeon in medical charge. Doubtless as ships full of wounded and sick came crowding into harbour Willoughby would have revised his estimate for both building and staff—we know in fact that he was soon engaging several temporary surgeons in haste. But any who may have lost themselves in that great maze of brick and banisters, the Royal Naval Hospital, Haslar, will smile at the thought of its first conception, with a respectable married couple as caretakers.

CASUALTIES LANDED ON THE EAST COAST

What Whistler had to say he usually wrote down simply in his own clear handwriting, but he showed a little more emotion when writing of his most distinguished patient who had been wounded in the fight:

> "General Blake I hope mends, but I am checked from too presumtuous prognostics by that maxim *de senibus non temere sperandum*; it is the prerogative of the Great Physician in Heaven to presage life or death according to His secret decree, a ray of whose all-seeing knowledge appears but dimly to us through narrow crannies of conjectural guess."

When the East Coast became the base line, administrative difficulties increased, for casualties (which were heavier) might be landed in any of the small creeks and havens between Great Yarmouth and the Thames Estuary. Fortunately there was now a good supply of surgeons, and the people of East Anglia generally seem to have been helpful, doubtless inspired by the presence of Elizabeth Alkin who (two hundred years before Florence Nightingale) wore herself out in tending the wounded. Writing from Harwich to the Admiralty, she explains that her funds were exhausted in having the wounded "cleansed in their bodies and their hair cut, mending their clothes, reparations and several things else, so that I have spent both the money I had of you and my own money; and besides I am owing for my diet." In the last letter we have of this devoted woman, now broken in health and devoid of means, she is asking to be admitted to a hospital wherein to end her days in peace.

As at Portsmouth Whistler had always had the Commissioner's help in any scheme benefiting the seamen, so now he knew he could look for the same ready assistance from Nehemiah Bourne who ruled at Harwich. Bourne has left it on record that he knew the Lord of Hosts was interesting Himself on England's behalf in the war; he would have had none of the young doctor's "narrow crannies of conjectural guess," being himself on much more intimate terms with the Almighty; nevertheless religious enthusiasm never blunted his native shrewdness or his enthusiasm for hard work. Whistler's scheme was to concentrate the wounded in Ipswich, and very soon Nehemiah, whose principal business was the repair of broken ships, was providing the necessary transport, putting his shoulder to the wheel in aid of the man whose main business was the repair of broken men.

Then Whistler had the confidence of the Generals at Sea. Blake was soon again to come under his medical care, while Monck, now alone at sea in the *Resolution*, was writing to the Admiralty asking them to hasten Whistler down to take charge of the wounded. To show confidence in a man was to George Monck's way of thinking the highest form of praise.

The first Dutch war has been described by naval historians as the best conducted of any in which our country has been engaged. The evidence certainly gives us a picture of a hard-working administration ashore supporting a hard-hitting Fleet at sea. Those who know the papers relating to the war against Spain know how popular history books conceal the incredible meanness with which wounded seamen were treated after the defeat of the Armada; they know how Howard of Effingham manifested his true nobility by protesting against it, and how, so far as his own fortune would allow, he attempted to mitigate their hard case. Those who know the story of the early Stuart Navy will recall that, while we may hope there were the best intentions in high places, ignorance and corruption brought them to nought, and conditions at sea were worse even than in the days of Queen Elizabeth. But now at last it must have appeared to the seamen that the good intentions in high places had been accompanied by a very happy choice of men to carry them out. Daniel Whistler was of that good company, and when in 1684 they buried him in Christ Church, Newgate Street, perhaps the Naval Medical Service might think there was buried one whose name should be remembered with respect. RURAL HEALTH PROBLEMS IN CHINA

E. TUCKMAN
M.B. Lond., D.C.H., D.T.M. & H.
LATE MEMBER, FRIENDS' SERVICE UNIT (CHINA)

WESTERN medicine was introduced into China over a century ago, and the training of doctors in the universities established in the large towns has closely followed the pattern in this country. In the whole of China, however, fewer than 20,000 students have graduated, and the total number of hospital beds is less than 40,000. Because of the high cost of general and medical education most doctors came from well-to-do families, and they have practised almost wholly in the large towns and smaller ports where private practice was available and where living standards were far higher than in the countryside. In the rural areas, where more than 85% of the country's 475 million people live, medical services have been virtually non-existent.

THE OLD CHINA

In 1947 I went to do medical relief work in Honan province in central China, territory then under the control of the Kuomintang. Society was entirely feudal, and the illiterate peasants, who were mostly tenants of big landlords, lived in scattered villages with houses of mud, or mud and brick. In these single or two roomed houses lived the peasant and his family and often, too, his ox—if he was rich enough to own one. Many families kept a pig or a few chickens. Agricultural methods were extremely primitive and the only implements were a simple wooden plough, a harrow, and a hoe. Basic sanitary measures in the villages were unknown. Water was obtained from open shallow wells, and the same wooden bucket might be used to draw water for the peasant and his animal or even to carry nightsoil. There were no latrines, and human and animal excreta were stored in the open to be scattered on the fields as fertiliser.

Local government was by a system of appointments. The governor of a province appointed the *shienn* (county) magistrate, who in turn appointed all the officials within the *shienn*. Heavy taxation—in 1948 this amounted to over 70% of the total crop—and high rents made it impossible to build up reserves and raise the standard of living. The peasant was a prey to the extortions of bandits and the demands of corrupt local civil and military officials. The only medical services available to him were those of the local herbists whose methods included cupping, leeching, and the application of hot plasters. Needling was a common practice, partly because it was believed that the needle made a pathway along which the evil spirits could escape, and partly because of the popularity of injection therapy. In the drug shops of the larger villages there were small supplies of Western drugs, such as the sulphonamides, calcium gluconate, and arsenicals, and these could be bought for self-medication or for injection by a herbist. But their cost was prohibitive to all but the richer landlords and merchants.

Against such a background it is not surprising to find a crude mortality-rate estimated at between 25 and 30 per 1000—that is an excess mortality of at least 15 per 1000 population. Part of this excess is accounted for by the infant mortality, usually estimated as at least 200 though it is undoubtedly much higher in some areas, and a maternal mortality varying between 15 and 20 per 1000 live births. The remainder is due mainly to gastro-intestinal disease, pulmonary tuberculosis, and the infections of childhood, particularly smallpox and diphtheria, which are common throughout the country. In addition, there are the main endemic killing diseases—kala-azar in the north, schistosomiasis in the centre, and malaria in the south—and the frequent epidemics of cholera, enteric, typhus, and plague. Crude morbidity is estimated at 4% of the population, so that every day there are nearly 20 million people who are ill. This morbidity is greatly increased by trachoma, which affects over a third of the entire population, and venereal disease, with an incidence of nearly 10%. Helminth infestation is widespread, some hundreds of thousands suffer from filariasis, and probably over a million have leprosy. Vitamin, protein, calcium, and iron deficiencies are rampant.

AND THE NEW

In the autumn of 1948 I went with a small team across no-man's-land into one of the border regions of the "liberated areas"—the name given to the districts where the Communists had taken over control from the Japanese or from the Kuomintang. There both military and economic conditions were stable. Beggars and bandits had disappeared. Under land reform, carried out by peasants' unions, landlordism had been abolished and the land distributed, roughly on a basis of half an acre per member of family, to anyone willing to work it. There was no collectivisation; each peasant held the title deeds to his own land, and women, who had complete equality, held land in their own right. As a result of the introduction of mutual-aid cooperatives, and of the establishment of schools for the peasants where they were taught improved methods of agriculture, food-production had increased by nearly 10% over the previous year. Taxes in 1949 amounted to about 23% of the spring wheat, the main crop. Elections had recently been held in the villages for local-government officials, among whom corruption was unknown, and these in turn had elected *shienn* representatives to the North China People's Congress.

My team was to try to deal with an epidemic of kala-azar. The border region in which we were to work had about 20,000 cases, an incidence of roughly 3% of the population. There were no suitable drugs in the border region and we took with us enough antimonials and aromatic diamidines to treat 8000 cases. Later, further supplies were transported so that all the 20,000 could be treated. The local-government officials were extremely coöperative, welcoming anybody who was, as they said, "willing to work for the people." They provided us with food, accommodation, and transport. We set up our clinic in a small village and the local government sent messages to all the other villages in the *shienn* announcing our arrival. Needless to say, many patients with diseases other than kala-azar arrived and if we had the time or the drugs we treated as many as we could. Ferrous sulphate, for example, was given to patients with iron-deficiency anæmia, but these patients were so numerous and the supply of ferrous sulphate so limited that the drug was reserved for those with hæmoglobin levels of less than 40%. During the six weeks that we stayed in one village over 200 operations for entropion were performed, besides many other surgical procedures.

The public-health department sent four doctors, graduates of the medical school of Yenan (for many years the Communist capital), to be trained as leaders of mobile teams for the diagnosis and treatment of kala-azar. Twelve student nurses were also sent for training and eventually four more mobile teams were set up. Our team provided the drugs and the public-health department supplied some of the equipment such as sterilisers and stills, which could be made locally. The aim of the campaign was to cover the whole area and to treat all the cases within a year, in the hope that this would decrease the epidemic proportions of the disease. Treatment was free of charge, and the peasants were grateful for the work we were doing to save the lives of their children; for our course of injections converted a 95% mortality into a 90% cure-rate.

A PREVENTIVE SERVICE

During my stay in the liberated areas, I met many of the leaders of the new public-health department and they showed themselves fully aware of the enormous problems facing them. Their first aim was to try to reduce the excess mortality, which it was felt could be done without the establishment of a curative medical service. Indeed, a countrywide curative service—taking the low figure of 2 hospital beds per 1000 population—would require almost 1 million beds, a demand far beyond the resources of the present economy. Hence, though some development of the hospital services is taking place, the emphasis is being laid on preventive measures. The importance attached to anti-epidemic work, for example, may be judged from the fact that the chairman of the central anti-plague committee of the newly established State administrative council is a vice-premier of the central government. This committee has recently dealt with an outbreak of plague in Chahar province, and as a result of the vigorous measures of control used only 144 cases occurred, whereas during the epidemic of 1947 there were over 30,000 cases. Insecticides were not available but a cordon sanitaire was created by the use of inoculation and the destruction of 15 million rats. In Manchuria during the summer and autumn of 1949 nearly 8 million people, a fifth of the total population, were inoculated against cholera, typhoid, and plague.

In many parts of the country the development of rural health services under the new government has yet to begin. But an indication of the shape they will probably take is given by the rural health services that were being established in the area under the jurisdiction of the North China People's Government (now merged with the central government) before the large towns had been captured. This area, stretching from the Great Wall in the north to the east–west Lung-Hai railway in the south, is roughly the shape and size of England and has a population of about 64 million. The plan in 1949 was to set up at least one hospital in each of the hundred or so *shienn* into which the area was divided, and by August nearly 120 had already been established. It had not been possible to put up new buildings, but disused temples, the brick homes of absentee landlords, or even the mud houses of the peasants themselves had been adapted. The only equipment to be had was that made from local materials, though some surgical instruments had filtered through the Kuomintang blockade. Drugs were very scarce, and many, such as antimonials, antibiotics, and insecticides, were almost unobtainable. Some hospitals were entirely free of charge, but in areas where land reform had been carried out the patients were usually required to pay for their medicines, though there was no charge for registration, advice, or investigation. In newly liberated areas where the land had not yet been distributed poor peasants could get free medicines on presenting a letter from a local-government official.

EDUCATION OF DOCTOR AND PATIENT

Part of the staff of the new hospitals had come from the new graduates of the North China Medical College attached to the First International Peace Hospital. This hospital, originally established in the caves of Yenan, was situated just outside the town of Shihchiachuang which was the first big town in north China to be captured by the Communists. The buildings which housed the department of surgery had been constructed by the Japanese when they were occupying the town, but a good deal of damage had been done by bombing and by the retreating Kuomintang. The department of medicine was housed in neighbouring villages, and altogether there were some 800 beds. The staff, which included a number of Japanese doctors, were adept at improvisation and keen to learn especially of new developments, since they had been cut off from all sources of literature for many years. A round-table discussion with them on kala-azar, for example, resolved itself into my being "ragged" for nearly four hours. I was invited to lecture to the senior students in the medical college and was surprised to find the hall filled with some 350 young men and women who sat attentively through three lectures each lasting about three hours. There were many questions at the end, and in Kaifeng, where I repeated these lectures to a similar group of students at the medical school of the Central Plains University, medical questions were interspersed with some on politics and religion.

There were over 1000 students in the medical college at Shihchiachuang. Their course lasted three and a half years, eighteen months being spent in preclinical studies, one year in clinical subjects, and one year as an intern. This course was recognised as being too short for the training of highly skilled personnel, but because of the vast field to be covered the immediate emphasis was, inevitably, on numbers. When, later, the large university towns were captured, this shortened course of training continued alongside the lengthier course given in the old medical schools. In the countryside, old-style feudal doctors, who often had a rich experience in the use of local medicines, were regarded as a valuable adjunct to the medical services, and it was found that they readily absorbed modern medical knowledge. The aim was to unite modern medicine with what was good in their methods, and to educate these old-fashioned doctors to rid themselves of their superstitions.

Schools of nursing and of midwifery had been established, and village health workers were given a course in on much more intimate terms with the Almighty; nevertheless religious enthusiasm never blunted his native shrewdness or his enthusiasm for hard work. Whistler's scheme was to concentrate the wounded in Ipswich, and very soon Nehemiah, whose principal business was the repair of broken ships, was providing the necessary transport, putting his shoulder to the wheel in aid of the man whose main business was the repair of broken men.

Then Whistler had the confidence of the Generals at Sea. Blake was soon again to come under his medical care, while Monck, now alone at sea in the *Resolution*, was writing to the Admiralty asking them to hasten Whistler down to take charge of the wounded. To show confidence in a man was to George Monck's way of thinking the highest form of praise.

RURAL HEALTH PROBLEMS IN CHINA

E. Tuckman
M.B. Lond., D.C.H., D.T.M. & H.
LATE MEMBER, FRIENDS' SERVICE UNIT (CHINA)

Western medicine was introduced into China over a century ago, and the training of doctors in the universities established in the large towns has closely followed the pattern in this country. In the whole of China, however, fewer than 20,000 students have graduated, and the total number of hospital beds is less than 40,000. Because of the high cost of general and medical education most doctors came from well-to-do families, and they have practised almost wholly in the large towns and smaller ports where private practice was available and where living standards were far higher than in the countryside. In the rural areas, where more than 85% of the country's 475 million people live, medical services have been virtually non-existent.

THE OLD CHINA

In 1947 I went to do medical relief work in Honan province in central China, territory then under the control of the Kuomintang. Society was entirely feudal, and the illiterate peasants, who were mostly tenants of big landlords, lived in scattered villages with houses of mud, or mud and brick. In these single or two roomed houses lived the peasant and his family and often, too, his ox—if he was rich enough to own one. Many families kept a pig or a few chickens. Agricultural methods were extremely primitive and the only implements were a simple wooden plough, a harrow, and a hoe. Basic sanitary measures in the villages were unknown. Water was obtained from open shallow wells, and the same wooden bucket might be used to draw water for the peasant and his animal or even to carry nightsoil. There were no latrines, and human and animal excreta were stored in the open to be scattered on the fields as fertiliser.

Local government was by a system of appointments. The governor of a province appointed the *shienn* (county) magistrate, who in turn appointed all the officials within the *shienn*. Heavy taxation—in 1948 this amounted to over 70% of the total crop—and high rents made it impossible to build up reserves and raise the standard of living. The peasant was a prey to the extortions of bandits and the demands of corrupt local civil and military officials. The only medical services available to him were those of the local herbists whose methods included cupping, leeching, and the application of hot plasters. Needling was a common practice, partly because it was believed that the needle made a pathway along which the evil spirits could escape, and partly because of the popularity of injection therapy. In the drug shops of the larger villages there were small supplies of Western drugs, such as the sulphonamides, calcium gluconate, and arsenicals, and these could be bought for self-medication or for injection by a herbist. But their cost was prohibitive to all but the richer landlords and merchants.

Against such a background it is not surprising to find a crude mortality-rate estimated at between 25 and 30 per 1000—that is an excess mortality of at least 15 per 1000 population. Part of this excess is accounted for by the infant mortality, usually estimated as at least 200 though it is undoubtedly much higher in some areas, and a maternal mortality varying between 15 and 20 per 1000 live births. The remainder is due mainly to gastro-intestinal disease, pulmonary tuberculosis, and the infections of childhood, particularly smallpox and diphtheria, which are common throughout the country. In addition, there are the main endemic killing diseases—kala-azar in the north, schistosomiasis in the centre, and malaria in the south—and the frequent epidemics of cholera, enteric, typhus, and plague. Crude morbidity is estimated at 4% of the population, so that every day there are nearly 20 million people who are ill. This morbidity is greatly increased by trachoma, which affects over a third of the entire population, and venereal disease, with an incidence of nearly 10%. Helminth infestation is widespread, some hundreds of thousands suffer from filariasis, and probably over a million have leprosy. Vitamin, protein, calcium, and iron deficiencies are rampant.

AND THE NEW

In the autumn of 1948 I went with a small team across no-man's-land into one of the border regions of the "liberated areas"—the name given to the districts where the Communists had taken over control from the Japanese or from the Kuomintang. There both military and economic conditions were stable. Beggars and bandits had disappeared. Under land reform, carried out by peasants' unions, landlordism had been abolished and the land distributed, roughly on a basis of half an acre per member of family, to anyone willing to work it. There was no collectivisation; each peasant held the title deeds to his own land, and women, who had complete equality, held land in their own right. As a result of the introduction of mutual-aid cooperatives, and of the establishment of schools for the peasants where they were taught improved methods of agriculture, food-production had increased by nearly 10% over the previous year. Taxes in 1949 amounted to about 23% of the spring wheat, the main crop. Elections had recently been held in the villages for local-government officials, among whom corruption was unknown, and these read all the current views on sympathectomy, which ranged from extreme optimism to extreme pessimism.

After some months of indecision, being a Catholic, I decided to visit the shrine of Our Lady of Lourdes to pray for guidance. In July, 1949, I made the pilgrimage with some six hundred pilgrims from Liverpool. The weather during our ten days in France was intensely hot and, remembering my Army category of "B non-tropical," I was surprised when I took a bath at the piscine to note that my head was not immersed.

On the second day after my return home (it must have been Aug. 7) I was sitting on the edge of my bed before retiring when I had a very severe frontal headache spreading over the top of my head accompanied by a strange sensation like water running down the back of my neck, and followed by a violent rigor. Being already in my pyjamas I just tumbled onto my side and went into a heavy sleep. Next morning, when on my way to the bathroom, I must have fallen asleep in an armchair in the dining-room, where with great glee my two-year-old son found me.

For two days I stayed in bed, confused and disorientated regarding the passage of time, with photophobia and neck rigidity and occasional vomiting. On Aug. 10 I was admitted to the local hospital, where lumbar puncture confirmed a diagnosis of subarachnoid hæmorrhage. I remained semistuporose, with a slight rise of temperature, for about a week. I had no motor disability, apart from an inability to begin micturition unless my bladder was very distended (on one occasion I broke the ward record with 46 oz.). My memory for names and recent events was very poor, and for the first week I seemed to have little grasp of my situation—I had even insisted on walking to the ambulance. I recovered quickly, however, and decided to have a thoracolumbar sympathectomy as soon as it could be arranged. Three weeks later I was transferred to my old hospital again, little the worse for my experience. I had an occasional local and postural headache, with tenderness of the scalp in the same area, though I had had no injury. My peak B.P. was 250/170 mm. Hg.

* * *

My kidney-function tests were again satisfactory, and with the aid of 'Omnopon' and hyoscine and the sweetest 'Pentothal' induction my right side was sympathectomised in early September. I awoke to a severe pain in my right ribs, hæmaturia (from kidney biopsy), and bloodstained sputum. The next week was not very pleasant. The continuous pain on the right side of my chest made sleep almost impossible, despite sedatives, and being turned at night by vigorous young women was anything but a pleasure, so I soon forestalled nursing eagerness by turning myself with the aid of the chain handle and found I could use my shoulder muscles without discomfort. There was no vomiting or even any nausea.

Besides the pain in my chest I had frequent severe toothache-like abdominal pains, which seemed to move all round the abdomen and defy accurate description; they were made worse by cold and I was hypersensitive to draught. There was also an ulcer-like persistent tenderness in my right epigastrium and a general hyperæsthesia and tenderness of my whole abdomen on the right side. No doubt these pains were largely due to the unavoidable traction on posterior nerve-roots at the operation.

My B.P. fell to 190/111 mm. Hg for a day or two after the first stage but soon returned to a little below its previous average. I left hospital two weeks after the operation, still having aches and pains.

After three weeks at home, I returned to hospital, for the last hurdle. My abdomen was still sufficiently tender and hyperæsthetic on the right side to prevent me wearing elastic-topped under pants, and my ribs still ached considerably.

After further renal-function tests the second stage was done. I was given a blood-transfusion for the sharp fall in B.P. which occurs immediately after the operation, and the consolidation and effusion at the base of the left lung, with foul purulent sputum, which developed in the next few days responded as though by magic to penicillin. My B.P. remained at a normal figure for about ten days but soon rose again to 180/140 mm. Hg. I had the same abdominal pains as after the first stage but they seemed less severe and the epigastric tenderness was bilateral. I have read somewhere of a patient after sympathectomy feeling that he was suspended in mid air; I felt that my bed was not in its corner but half way down the ward, and in my memory of events during the first few days after operation it still occupies that position.

A fortnight after the second stage I was standing by my bed, but I soon realised I had postural hypotension (a good prognostic sign). This condition is not often met with outside neurosurgical wards, and the younger nurses seem to look on it as a vague psychogenic visitation calling for encouragement, exhortation, and sometimes stimulation. In fact it is purely physical, and the only immediate treatment needed in an attack is a change of posture. On standing upright one's radial pulse becomes increasingly rapid and shallow: there is a feeling of tenseness in the chest and breathlessness soon follows. Next one's vision becomes blotchy and if one is wise one quickly sits down with bent head. My B.P. in the arms was 90/60 mm. Hg when standing and 180/120 when lying down. I soon found, however, that I could remain upright without symptoms while walking rapidly short distances from chair to chair. By lengthening the distances I made gradual progress, and by three weeks after the operation I could wander up and down the ward, resting if necessary on the way. An abdominal binder was of some help at this stage.

I was now sent to a convalescent home in the country, where I could soon walk increasing distances without distress and before long managed a mile or so, keeping an eye open for a suitable seat (a shooting-stick would have been ideal). There were four psychosomatic "gastric" bus-drivers in my ward who should have had their mothers-in-law removed instead of their stomachs. We five used to go into the nearby town for recreation, and on these trips I discovered two useful methods of combating the postural hypotension.

The more effective of the two was to keep one's legs moving. When waiting in bus or cinema queues I either marked time or swayed from one leg to the other. The weather was cold at the time so these manœuvres did not attract much interest, though some people may have wondered why I did not avail myself of the nearby gentlemen's sign. The second method was by rhythmical contraction and relaxation of the abdominal wall. This, I feel, would have been the more effective had not my muscles been flabby and my abdomen tender at the time, so that the contractions were somewhat inadequate and the process laborious.

On Dec. 19, nine weeks after the second stage, I resumed work on a half-time basis and six weeks later I was working full-time again. The postural hypotension has now almost completely disappeared and is only noticeable on getting out of bed first thing in the morning, after standing still for more than five minutes at a time, and on standing after moderate exercise such as walking up several flights of stairs.

My back still aches slightly, particularly in damp cold weather. Among the other aches and pains one experiences after this type of sympathectomy is an ache in the thighs and an occasional one in the cords and testicles. There also appears to be an overactivity of the remaining sympathetic, making one's hands specially sensitive to cold and often giving one pins the principles of sanitation, disease prevention, and health education. Most of these courses lasted six months to a year, though some workers had only a three-month course. Most of the students were from peasant families, and they received not only free tuition but also full maintenance during their training. Teaching in foreign languages had been abolished, and education was continued after training by the distribution of literature and at frequent area conferences. All those working in the public-health department were full-time salaried employees—except Communist party members, who received no salary. There was no private practice.

Throughout the whole integrated plan emphasis was laid on close contact with the people and on the health education of the villagers. Midwives went into the villages not only to assist in deliveries, but also to train the old-style midwives in modern methods. Only everyday articles, obtainable in every village, were used, so that the local midwives could carry on after the trained midwives had left. Here the main emphasis was, of course, on the value of sterilising equipment, either by boiling or by using the locally brewed *baigar*—a liquor containing about 70% alcohol. Popular education was carried on by midwifery students who took a puppet show round the villages, and sang, in the style of the classical minstrels, their information on the prevention of tetanus neonatorum and on other subjects. Each *shienn* had a mobile team who could deal with an emergency or epidemic, and these, in coöperation with the village health workers, drew the peasants themselves into the task of securing and maintaining hygienic conditions. As a result, villages challenged each other for the title of "cleanest village in the district."

The Chinese peasant on the whole judges by results, and the obvious efficacy of the new methods soon breaks down any resistance he may offer to the introduction of new ideas. A little resistance was, however, met. Some peasants, for example, refused the free vaccination offered them during the spring anti-smallpox campaign on the grounds that vaccination should be performed only after the *chingming* solar period had passed. Others refused to believe in the value of a single linear insertion and demanded three areas of multiple insertions on each arm. Nevertheless hundreds of thousands were vaccinated. Great help in popular health education and in breaking down superstititions was given by simple articles and explanations in the daily newspapers—and by the new adult education classes where the peasants learned to read them.

CONCLUSIONS

The long-term solution of China's health problems depends on raising the standard of living of the whole population, on developing education, and on bettering social and economic conditions. These in turn depend on changing the country's economy from a predominantly agricultural to a predominantly industrial one. At present only 10% of China's production is industrial, and the declared aim of the new government is to raise this figure to 40% within fifteen to twenty years. There is little doubt that with this change the country's medical services in both rural and urban areas will develop rapidly.

Disabilities

47. PRIMARY CHRONIC HYPERTENSION; SUBARACHNOID HÆMORRHAGE; SYMPATHECTOMY

At the age of 34 I feel that my hypertension has been neither benign nor essential, so I shall call it primary chronic hypertension. Both heredity and environment have undoubtedly played their part in my case. Several of my forebears on either side have died before their allotted span with cerebral catastrophes; and which of us these days can claim that his environment has been free from stresses and strains. But far harder to bear than the tangible fears based on these reasonable foundations has been the more personal fear of the obsessional.

I have known of my hypertension since my student days, when its discovery aroused unwelcome interest in a drab practical physiology session. I have always felt hypertensed, but it did not obtrude much into my everyday life; I played for my hospital at cricket and soccer and generally led a full existence.

The Army graded me "B non-tropical," so I spent over 3¼ years in training and detention camps, with P.T. at 7 A.M. thrown in as a fillip. However, I survived, with occasional check-ups on my B.P., until the Christmas before war ended, when one night on washing my teeth I noticed that my tongue deviated to the right, and however hard I tried I could not fold it up longitudinally or push it to the left. I remembered then that in the afternoon there had been a slight slurring and clumsiness of my speech when lecturing. I reported sick a few days later and was rushed off to a military hospital labelled: "? Rt. hypoglossal palsy. ? due to diphtheritic neuritis. ? Hypertensive spasm." Diphtheria had been prevalent in the camp, but swabs proved negative and there was no clinical history of illness. My B.P. at this time was 230/150 mm. Hg. My paresis recovered completely in about a week. My hypertension was investigated thoroughly, and a considered diagnosis of hypertensive spasm was made. The war was all but over, so I was given two months' sick-leave and discharged medically unfit. With rest my B.P. had fallen to 180/120.

After a short spell in general practice I became an assistant medical officer at a mental hospital, which job I have held ever since, apart from six months as a supernumerary registrar at my alma mater. My B.P. remained a little above 180/120, and I still played some good games of mental hospital cricket, though running rather taxed my powers and I was too short-winded for soccer.

* * *

In our hospital it was the practice to hold a daily "office," first thing in the morning, when the staff congregated in the superintendent's room to discuss any matter of importance. In a quiet moment I tested my visual fields on a large calendar on the wall opposite and found that with each eye separately some of the figures appeared to have pieces missing. I consulted the eye specialist on his next visit and he confirmed my fear that there were some slight exudates in both eyes, but he could see no hæmorrhages or papillœdema.

I decided to go into hospital for a full investigation with a view to sympathectomy, and in May, 1948, I returned as a patient to my old hospital. I was thoroughly investigated and was made to "rest" for three weeks—so far as rest was possible for a hypertensive in a general ward suffering the whole time from a severe post-lumbar-puncture headache which prevented me from sitting even half up in bed. There was, of course, no fall in my B.P.; on the average it was higher being about 200/130 mm. Hg. However, apart from an occasional trace of albumin in the urine, my kidney function was normal—as indeed it seems always to have been, for I have never had any renal trouble. My electrocardiogram showed inverted T waves. I was advised to have a sympathectomy, but I preferred to postpone the operation until I had recovered my steam.

I took my annual leave in Cornwall with my wife and four children, and then went back to work for the next year, with little change in my disability. I carefully right direction, though there was still no justification for rejoicing. Although the number of deaths went down last year notifications went up, but firm figures were not yet available. The increased notifications were no doubt partly due to better methods of diagnosis. For instance, within the next few weeks the number of mass radiography units in Scotland would be increased to 7. With increased notification and longer periods of hospital treatment, there had been a tendency for the waiting-lists to grow. But in the West of Scotland, where tuberculosis was worst, waiting-lists were decreasing, largely through the energetic efforts of the Western regional hospital board to provide additional beds. In the last 18 months the board had diverted some 250 beds, mostly in infectious diseases hospitals. This work was continuing, but not so rapidly as it would be if more nurses could be recruited for tuberculosis cases. Another development was the use of lightly staffed accommodation for patients able to look after their own needs.

The press reports of the Edinburgh conference, Mr. Fraser continued, were misleading. The impression was given that if 100 trained nurses could be got, 1000 additional beds would be available. But the speaker had in fact said " If 100 trained nurses, working together with part-time and part-trained nurses, could be got." But how many? He did not know. Again, the Press report gave the impression that their recruitment programme had met with no success. The truth, however, was that their sanatoria were now working almost to capacity, and to recruit more nurses for the sanatoria would not necessarily mean more people under treatment. But he did not deny that the great need was for nurses and he was glad to report that recruitment was steadily improving.

Mr. Fraser held that to segregate active tuberculosis cases in one corner of a housing scheme, or in a separate scheme, would be the worst possible thing from a psychological standpoint. It would be exceedingly difficult to get people to live in a colony of tuberculosis sufferers.

The Department were now offering B.C.G. vaccination to nurses and medical students, and, through local authorities, to known contacts. At present it was necessary to obtain the vaccine from abroad. Production difficulties had caused an unfortunate hitch. However, experts from this country had returned from a visit to Denmark from which country it was hoped to get vaccine. He was hopeful that supplies would be available shortly. The Department still regarded the treatment of tuberculosis as number one priority among Scotland's health problems.

QUESTION TIME

Crimes of Violence

Replying to questions calling attention to the recent increase in crimes of violence and brutality, and suggesting the introduction of legislation to provide for heavier penalties, Mr. CHUTER EDE, Home Secretary, said: The question whether the criminal courts should have power to award corporal punishment for offences such as armed robbery and robbery with violence is a controversial one, on which the differences of opinion do not follow party lines. The question was fully debated when the Criminal Justice Bill was recently before Parliament, and Parliament then decided to include a provision in the Bill taking away such power from the courts. I have no evidence which in my view warrants the reopening of the decision then reached.

Sir HERBERT WILLIAMS: Is the Minister aware that the number of women attacked by men armed with coshes is so large that it is time he adapted his mind to the circumstances now prevailing?—Mr. EDE: The number of offences that were punishable by corporal punishment before the alteration of the law has, in fact, fallen since its repeal. In the nine months to September 1948, there were 711 such offences. Corporal punishment was abolished on Sept. 13, 1948, and in the corresponding nine months of 1949 the number of offences for which this penalty could otherwise have been awarded fell from 711 to 597. Mr. ANTHONY MARLOWE: Does the Minister appreciate that his figures are quite fallacious in view of the fact that before the abolition of corporal punishment the indictment was specially drawn in a way which would make that punishment awardable, but that since then indictments have been differently drawn, and there is no deduction whatever to be drawn from these figures?—Mr. EDE: The hon. member did not quite follow what I said. I alluded to cases known to the police, not to indictments.

Capital Punishment and Prerogative of Mercy

Mr. SYDNEY SILVERMAN asked the Minister what were the considerations to which he has regard in deciding whether or not to advise His Majesty to exercise the Royal Prerogative of mercy in capital cases.—Mr. EDE replied: It is not desirable or possible to lay down hard and fast rules as to the exercise of the prerogative of mercy in capital cases, or to give, within the compass of an answer to a question, any adequate statement of the variety of considerations which may in practice be taken into account. Information as to certain general principles and as to the practice followed by successive Home Secretaries in some classes of cases was, however, given in the memorandum submitted by the Home Office to the Royal Commission on Capital Punishment.

Mr. LYALL WILKES: Is the Minister aware that since July, 1945, in 5 cases where juries made a strong recommendation to mercy the death sentence was still carried out? Would not the Minister agree that as the jury probably knew more about the case than anybody else, it would be advisable to treat strong recommendations to mercy as an expression of the jury's view that the man should not be hanged?—Mr. EDE: The fact that a strong recommendation to mercy is made by a jury is one of the factors that are given the most serious consideration, but after nearly five years' experience in this matter I cannot accept the doctrine that that should be a final and determining factor when the Home Secretary has to consider the decision he has to take. Mr. S. SILVERMAN: Is not the Home Secretary aware that in a number of recent cases the decisions made have caused the widest possible public anxiety and distress?—Mr. EDE: I have a duty to discharge which is exceedingly difficult and delicate. I am only too well aware that on occasions when I reach decisions, for reasons which I cannot disclose, there may be, in consequence, great misgiving in the public mind which would be removed if I could disclose my reasons. I am, however, precluded, and I think rightly precluded, from doing so.

Care of Chronic Sick

Mr. G. W. ODEY asked the Minister of Health if he was aware that under the National Health Service there is no adequate provision for the aged chronically sick, many of whom are in hospitals which are urgently needed for the treatment of sickness of a temporary nature?—Mr. ANEURIN BEVAN replied: There are far more facilities than were available before. All that is happening is that now the needs are becoming articulate.

Colonel M. STODDARD-SCOTT: Will the Minister restore to the local authorities the provision of accommodation for the chronically sick, so as to ensure that these victims of the National Health Service are properly cared for.—Mr. BEVAN: I am not prepared to accede to the request to restore the poor-law.

New Hospital at Cardiff

Mr. GEORGE THOMAS asked the Minister whether he would make a statement concerning the proposed new hospital in the Cardiff area.—Mr. BEVAN replied: Discussions are now taking place between the board of governors of the United Cardiff Hospitals, the university, and the city council, about a site for a new teaching hospital and medical school to replace the present inadequate premises of the Cardiff Royal Infirmary.

Unregistered Practitioners

Brigadier FRANK MEDLICOTT asked the Minister what decision he had made on the question whether insured persons should be entitled to receive alternative forms of treatment such as osteopathy, naturopathy, and herbalism.—Mr. BEVAN replied: In accordance with the decision of Parliament, medical services under the National Health Service Acts are provided only by registered medical practitioners.

and needles in the fingers. My skin is rather dry below the level of the nipples (T4), but as Boyd and Monro[1] always find after thoracolumbar sympathectomy, there is fortunately (from some points of view), an "escape area" of sweating on the lower abdomen, groins, perineum, and inner surface of the legs. The urine tended for a while to dribble slightly at the end of micturition but the flow is now normal, and my bowels, previously somewhat constipated, now move regularly. My feet are beautifully warm and my vision has improved. My body hair generally seems coarser.

I have abandoned the morbid contemplation of my blood-pressure; my neurosurgeon tells me that it is "well down," and I have hesitated to lift the lid of Pandora's box any further. I am less easily irritated and flustered, and altogether I feel the sympathectomy has done me good. I am deeply grateful to those whose skill made this extensive operation possible, to those who looked after me so well, and to my chief for his consideration throughout my long illness and convalescence.

---

Parliament

Cost of the Health Service

THE Vote on Account which was presented to the House of Commons on March 7 shows that the expenditure on the civil and revenue departments and the Ministry of Defence in 1950–51 will amount to £2375 million. The supplementary estimates amount to £148,402,365, of which £98,730,000 is needed to meet the excess over the estimated expenditure of £259,727,600 on the National Health Service in England, Wales, and Scotland. This will bring the total expenditure on the service for the year to more than £358 million from the Exchequer. The principal items in the supplementary estimate are: £48,395,000 for advances to regional hospital boards and boards of governors (original estimate £194,315,000); £17,744,000 for general dental services (original estimate £30,904,000); £14,550,000 for pharmaceutical services (original estimate £20,800,000); and £10,455,000 for supplementary ophthalmic services (original estimate £14,670,000). An additional £2,304,000 is required to meet liabilities transferred to the Minister of Health and the Secretary of State for Scotland, compared with the original estimate of £2,258,000.

Midwives (Amendment) Bill

This Bill was introduced and read a first time in the House of Lords on March 8.

School-children and the Health Service

In the House of Commons on March 8 Mr. GEORGE THOMAS urged that school-children should have priority for spectacles as they used their eyes more than adults. He was also perturbed by the serious delay in giving children dental treatment. For instance, the school medical officer for Cardiff reported that 2169 children had teeth which needed filling, and 3340 cases were awaiting extractions, of whom about 1000 actually had toothache. Could not an approach be made to the dental profession to ask if they could get the local dentists to give some sessions to school work? Could not new entrants to the profession serve a minimum period in schools?

Colonel M. STODDART-SCOTT said that before the National Health Service was introduced children were able to get not only ordinary spectacles, but splinterless spectacles which the N.H.S. had never yet provided. School-children were actually the victims of the service. Before the N.H.S. was introduced, he continued, there was 1 dentist for every 3000 children in the schools. Today, in spite of the fact that the Act instructed the Minister of Health to provide a priority dental service for the schools, there was only 1 dentist for every 6000 children.

Mr. ARTHUR BLENKINSOP, parliamentary secretary to the Ministry of Health, said that it had been agreed between the opticians, the manufacturers, and the Ministry that a 5% priority scheme would be reasonable if speedy delivery was to be assured in the most urgent cases. It was also agreed that the only person who could choose priority cases was the optician. Later it was found possible to increase the priority figure to 7½%. It was then agreed that the priority category should include children whose eyesight would particularly suffer from delay. All school-children in need of glasses could not be included be [illegible] to bring in other groups also [illegible] particularly those working in industry. This scheme had been successful on the whole. They had imported from abroad something like one million lenses, but the proper solution was obviously to improve the production of lenses by British manufacturers. During last quarter we had in fact produced some 33% above demand, and delays were being steadily reduced. Before long it was hoped to abolish the priority scheme altogether though there might still be some difficulties in the supply of special lenses, especially bifocal lenses, owing to lack of specially trained labour. It was possible under the health service to provide splinterless glasses where they were medically necessary, and these glasses were not provided automatically free under the old service.

The difficulty in the dental service, Mr. Blenkinsop said, arose from a shortage of dentists. Many had unfortunately been attracted into private practice by the higher rate of payment. Every effort was being made to train more dentists, but, of course, that was a long-term solution. In the meantime, some local authorities had secured the part-time services of practising dentists on a sessional basis. The position varied very much from one part of the country to another, but where there were difficulties the Ministry hoped that the local education authority, together with the local professional committees, would approach practising dentists to secure, if possible, their coöperation.

Mr. H. M. KING suggested that dentists might be required to undertake one or two sessions of school dental service as part of the condition of their going into the dental service.

Tuberculosis in Scotland

In the House of Commons on March 9 Mr. JOHN RANKIN called attention to the grave problem of tuberculosis in Scotland. A committee of the British Medical Association, which lately met in Edinburgh, had, he understood, charged the Department of Health with complacency in their approach to the problem. According to experts, if 100 trained nurses could be obtained about 1000 beds could be made available, thus breaking the back of the problem in Scotland. If the solution was as simple as that, 35,000 sufferers in Scotland, of whom only 4000 were in hospital or isolated, would look forward to the future with a hope which he trusted would not be shattered. Mr. Rankin also suggested that extra diet be provided for young women in the susceptible age-group of 17–25; and that the possibility of setting aside special accommodation for the tuberculous in new housing schemes might be further considered.

Mr. THOMAS FRASER, joint under-secretary of State for Scotland, agreed that tuberculosis was the least satisfactory feature of the health of Scotland. Why Scotland's record was far worse than most other Western European countries since the war remained obscure, but he understood that the committee, set up some 18 months ago to investigate the incidence of tuberculosis in Scotland, was on the point of presenting its report.

One new and encouraging fact was that for 1949 the Scottish death-rate from respiratory tuberculosis was 10% below the 1948 figure, and at 59 per 100,000 of the population was the lowest since 1939. When non-respiratory tuberculosis was added, the total death-rate of 67 per 100,000 of the population was the lowest ever recorded. Movement, he claimed, was thus now in the

Letters to the Editor

PHYSICAL ACTIVITY AND PARALYSIS IN POLIOMYELITIS

SIR,—I am glad that you found space to comment in your leading article last week, on Dr. Horstmann's[1] excellent paper. There is one practical point which I should like to add to this story of the danger of carrying on after the onset of the preparalytic stage.

One would have thought that when muscles are actually losing strength, most patients would be content to lie quietly and leave the battle to nature, but not so. I have been distressed to find on questioning several desperately paralysed patients that, far from resting while paralysis was developing, they have decided that they should keep their limbs moving till they will move no more. Almost the last remark of one young woman before she died was "at least I have kept my arms moving." In some of these cases paralysis continued to spread for three or four days—longer than is usual—while the patient struggled desperately to keep the limbs moving. Not only, therefore, should the patient go to bed at the onset of the preparalytic stage, but *he should be told to lie quite still and to use his muscles as little as possible.*

Oxford.　W. RITCHIE RUSSELL.

AUREOMYCIN AND RELAPSING FEVER

SIR,—The following are the findings in eight cases of relapsing fever treated with 'Aureomycin' which I have been able to keep under close observation:

Of the 8 cases, 4 were in adults aged 18–25 years, and 4 in children aged 2–14 years. All were Africans from this region. Some had never been bitten by house-ticks (*Ornithodorus moubata*) until recently and some had lived in tick-infested houses in childhood but in recent years had not been exposed to contact with ticks.

All the patients were acutely ill when the diagnosis was made, and in all cases the diagnosis was made by the finding of *Borrelia duttoni* in blood-smears. Temperatures at the time parasites were found varied from 38·5 to 40°C: the average was about 39·5°C.

In the adults the average leucocyte-count at the time parasites were first found was 16,000 per c.mm.; in the children the average was 16,300 per c.mm. In 5 cases repeated differential leucocyte-counts were done, and they showed, at the time parasites were first found, pronounced neutrophilia and increase in staff (stab, band, "rhab") cells. The average for polymorphonuclear neutrophils was 77%, and for "stabs" 19%.

Treatment with aureomycin in capsules was begun as soon as the laboratory diagnosis was made, and the average dosage was 0·5 g. every 6 hours, by mouth. Treatment was continued on average for 6 doses.

In 4 of the cases the blood became free of treponema after one dose of aureomycin; in the other 4 the blood became free of treponema after the second dose. In 4 the temperature rose after the first dose; but in all the temperature returned to normal in 6–14 hours: the average time taken for the temperature to fall to normal was 10 hours.

In the 5 cases where repeated differential counts were done it was found that 8 hours after treatment was begun neutrophils (polymorphonuclears and "stabs") averaged 66% of the total leucocyte-count. In all but 1 of these 5 cases there were 11% or more of monocytes; in these 5 cases the average percentage of monocytes when treatment was begun was 14. In 3 of the cases there was a well-marked rise in monocytes after treatment was begun; and 8–10 hours after treatment was begun the differential count still showed 14% of monocytes. The laboratory technician, Miss Frances Botham, drew our attention to the distinctive appearance of many of the monocytes, and smears have been sent to competent hæmatologists for study.

Apart from the rise in temperature and rigors noted in a few cases for several hours after the first treatment, results were most pleasing. The relief of symptoms and fall of temperature were dramatic. It seems apparent that in aureomycin we have found a most valuable therapeutic weapon for the combat of a very widespread, disabling, and often fatal, infection.

On behalf of our patients and the hospital staff I should like to thank Lederle Laboratories for providing a generous supply of aureomycin for experimental purposes.

CHOICE OF WEAPONS AGAINST INFECTIONS

SIR,—I read with great interest the leading article in your issue of March 4 on the choice of antibiotics in various infections. I feel, however, that one reason justifying combined therapy is worth elaborating in more detail.
